Power-line noise is typically a broadband type of interference, relatively constant across a wide spectrum. Since it is broadband noise, you simply can't change frequency to eliminate it. Power-line noise is usually, but not always, stronger on lower frequencies. It occurs continuously across each band and up through the spectrum. It can cause interference from below the AM broadcast band through UHF, gradually tapering off as frequency increases. If the noise is not continuous across all of an amateur band, exhibits a pattern of peaks and nulls at different frequencies, or repeats at some frequency interval, you probably do not have power-line noise.

The frequency at which power-line noise diminishes can also provide an important clue as to its proximity. The closer the source, the higher the frequency at which it can be received. If it affects VHF and UHF, the source is relatively close by. If it drops off just above or within the AM broadcast band, it may be located some distance away — up to several miles.

Power-line noise is often affected by weather if the source is outdoors. It frequently changes during rain or humid conditions, for example, either increasing or decreasing in response to moisture. Wind may also create fluctuations or interruptions as a result of line and hardware movement. Temperature effects can also result from thermal expansion and contraction.

Another good test for power-line noise requires an oscilloscope. Remember that power-line noise occurs in bursts most frequently at a rate of 120 bursts per second and sometimes at 60 bursts per second. Observe the suspect noise from your radio's audio output. (Note: The record output jack works best if available). Use the AM mode with wide filter settings and tune to a frequency without a station so the noise can be heard clearly. Use the LINE setting of the oscilloscope's trigger subsystem to synchronize the sweep to the line. Power-line noise bursts will remain stable on the display and should repeat every 8.33 ms (a 120-Hz repetition rate) or less commonly, 16.67 ms (60 Hz), if the gap is only arcing once per cycle. (This assumes the North American power-line frequency of 60 Hz.) See **Figure 27.7** for an explanation. If a noise does not exhibit either of these charac-

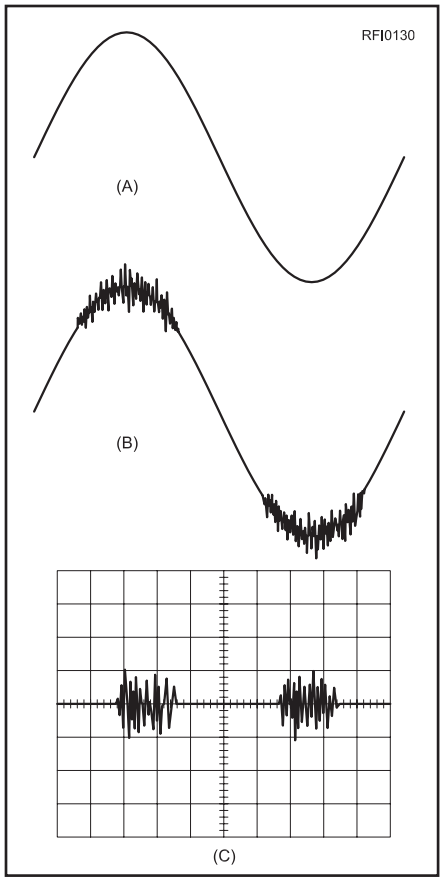

**Figure 27.7 — The 60-Hz signal found on quiet power lines is almost a pure sine wave, as shown in A. If the line, or a device connected to it, is noisy, this will often add visible noise to the power-line signal, as shown in B. This noise is usually strongest at the positive and negative peaks of the sine wave where line voltage is highest. If the radiated noise is observed on an oscilloscope, the noise will be present during the peaks, as shown in C.**

teristics, it is probably not power-line noise.

If a local TV station is transmitting analog TV signals on a lower VHF channel (very few remain as of early 2018), additional clues may be obtained by viewing the noise pattern on an analog TV set (if you still have one) using an antenna (not a cable TV connection). Power-line noise usually appears as two horizontal bars that drift slowly upward on the screen through the picture. (This is due to the difference between the NTSC signal's 59.94 Hz field rate and the 60 Hz power-line frequency.) As one bar rolls off the screen at the top of the display, a new one simultaneously forms at the bottom. In cases where the noise is occurring at 60 bursts per second, there will be only one bar on the display. In addition, the power-line noise bursts may have slightly different characteristics at the positive and negative peaks. This can cause each half of the cycle to have a slightly different pattern on the screen.

### ELECTRICAL NOISE

Electrical noise sounds like power-line noise, but is generally only present in short bursts or during periods when the generating equipment or machinery is in use. Noise that varies with the time of day, such as daytime-only or weekends-only, usually indicates some electrical device or appliance being used on a regular basis and not power-line noise. Unless it is associated with climate control or HVAC system, an indoor RFI source of electrical noise less likely to be affected by weather than power-line noise.

### ELECTRIC FENCES

A special type of electrical noise that is easy to identify is the "pop…pop…pop" of an electric fence. High voltage is applied to the fence about once a second by a charging unit. Arcs will occur at corroded connections in the fence, such as at a gate hook or splice. If brush or weeds touch the fence, the high-voltage will cause an arc at those points until the vegetation burns away (the arc will return when the vegetation re-grows). Each arc results in a short burst of broadband noise, received as a "tick" or "pop" in an HF receiver.

## 27.4.3 Identifying Intermodulation Distortion (IMD)

IMD products generated from the mixing of two strong signals in a non-linear junction or circuit appear at frequencies that are combinations of the two signal frequencies. The process of combination can occur outside or inside the receiver. The resulting IMD product signals include the modulation of both signals. For example, intermodulation from two SSB or FM voice signals produces somewhat distorted signals with the modulating signals of both stations. Since the two signals are not synchronized, the intermodulation products come and go unpredictably, existing only when both of the external signals are present.

### IMD GENERATED OUTSIDE A RECEIVER

Mixing of signals can occur in any non-linear junction where the original signals are both strong enough to cause current to flow in the junction. This is a particular problem at multi-transmitter sites, such as broadcast facilities and industrial or commercial communications sites. Non-linear junctions can be formed by loose mechanical contacts in metal hardware, corroded metal junctions, and by semiconductor junctions connected to wires that act as antennas for the strong signals. Non-linear junctions also detect or demodulate RF signals to varying degrees, creating interfering audio or dc signals in some cases. IMD products generated externally cannot be filtered out at the receiver and must be eliminated where the original signals are being combined.

An intermodulation product generated externally to a receiver often appears as an intermittent transmission, similar to a spurious emission. (See the **Receiving** chapter for more information on intermodulation.) It is common for strong signals from commercial paging or dispatch transmitters sharing a common antenna installation to combine and generate short bursts of voice or data signals. AM broadcast transmissions can combine to produce AM signals with the modulation from both stations audible.

An amateur station itself can be the source of strong signals that are picked up on various cables and wiring. The RF is then conducted into the station where it can encounter many types of diodes and transistors that act as the non-linear junctions. The resulting IMD product signals can then be conducted and radiated by the same cables and wiring that picked up the RF in the first place.

IMD can also be created in a broadcast FM or TV receiver or preamplifier. The solution is to add suitable filters or reduce overall signal levels and gain so that the strong interfering signal or signals can be processed linearly.

### IMD GENERATED INSIDE A RECEIVER

Since the products are generated internally to the receiver, the strong signals must be filtered out or attenuated before they can enter the receiver circuits in which IMD products are generated. Like external intermodulation products, those generated by a receiver acting non-linearly appear as combinations of two or more strong external signals. Intermodulation generated within a receiver can often be

## Common Mistake — The Source Must Be Illegal Because It's So Loud

The FCC limits for consumer electronics are not sufficient to protect against interference to nearby receivers. In a typical suburban neighborhood, the interference can be loud even from a neighboring residence. Proving they meet the applicable limits, these devices can be legally marketed and sold. If and when interference occurs, the burden then fall on the operator of the device to correct the problem.

Conclusion: Don't automatically assume that the device illegally exceeds the FCC limits just because it is causing harmful interference, even if it seems excessive. — *Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

detected simply by activating the receiver's incoming signal attenuator. If attenuating the incoming signals causes the intermodulation product to by reduced in strength by a greater amount than that of the applied attenuation, intermodulation in the receiver is a strong possibility. Since receivers vary in their IMD performance, differences in the interfering signal strength between receivers is also an indication of intermodulation.

The following simple "attenuator test" can be used to identify an IMD product, even in cases where it appears similarly in multiple receivers. This procedure applies mainly to superheterodyne receivers with analog circuitry in the sensitive front-end stages. SDR receivers respond to strong signals somewhat differently, with a more abrupt transition between linear and non-linear operation.

- If your receiver does not have one, install a step attenuator at its RF input. If you use an attenuator internal to your receiver, it must attenuate the RF at the receiver's input.
- Tune the receiver to the suspected intermod product with the step attenuator set to 0 dB. Note the signal level.
- Add a known amount of attenuation to the signal. Typically 10 or 20 dB makes a good starting point for this test.
- If the suspect signal drops by more than the amount of added attenuation, the suspect signal is an IMD product. For example, if you add 10 dB of attenuation, and the signal drops by 30 dB, you have identified an IMD product.
- You can also compare the reduction in signal level between the suspect IMD product and a known genuine signal with and without the added attenuation. Use a known genuine signal that is about the same strength as the suspect signal with no added attenuation. If the suspect signal drops by the same as the added attenuation, it is not an IMD product.

Intermodulation distortion can be cured in a number of ways. The goal is to reduce the strength of the signals causing IMD so that the receiver circuits can process them linearly and without distortion.

If IMD is occurring in your receiver, filters that remove the strong unwanted signals causing the IMD while passing the desired signal are generally the best approach since they do not compromise receiver sensitivity. (The chapter on **Receiving** discusses how to add additional filtering to your receiver.) Turning off preamplifiers, adding or increasing the receiver's attenuation, and reducing its RF gain will reduce the signal strength in your receiver. Antenna tuners and external band-pass filters can also act as a filter to reduce IMD from out-of-band signals. Directional beams and antennas with a narrower bandwidth can also help, depending on the circumstances of your particular problem.

### Common Mistake — Radiated vs. Conducted Emissions

The FCC does not impose radiated emissions limits below 30 MHz. There are only conducted emissions below 30 MHz. Specifically, the FCC requirements are for the RF conducted on the ac power connection, a power cord for most consumer devices. The limits in the case are expressed in terms of a voltage from both the phase (or "hot") conductor and neutral conductor to the ground conductor.

Note: Typical consumer devices are too small to be an effective antenna at HF. While the device may generate the RF, it doesn't radiate it. The actual radiation takes place from the wires and cables connected to the source device. The FCC rules in this regard only address the connection to ac power.

Above 30 MHz, the situation is reversed. There are no limits for conducted emissions — only for radiated emissions. The limits in this case are expressed as a field strength at a specified distance from the device. — *Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

## 27.5 Locating Sources of RFI

Once you have determined the *general* nature of the noise, it's time to find out where it's coming from. "Pinpoint the source precisely and you will know what it is." Good advice! There is no need to know exactly what the source is until it is found or narrowed down to a few possibilities. So the proper first question is, "How do I locate the source?"

Along with the material in this chapter, the Radio Direction Finding chapter of *The ARRL RFI Book*, describes the many methods available to locate sources. There are numerous websites with information about direction finding at all frequencies. This information helps educate the amateur that locating the source is the first step rather than speculating about what it might be.

Locating an offending device or noise source might sometimes seem like trying to find a needle in a haystack. With a little patience and know-how, it is often possible to find the source of a problem in relatively short order. RF detective work is often required and some cases require a little more perseverance than others. In any case, armed with some background and technique, it is often easier to find an offending source than the first-time RFI investigator might expect. Once the source is pinpointed and its exact nature is known, proper treatment can be applied to eliminate the RFI.

### PREPARING TO FIND A SOURCE OF RFI

Consider the following questions:

1) First and foremost, does the searcher have an open mind? This kind of search is not a visual search until the structure containing the source is located. Even then, equipment must still be relied upon to pinpoint the source. An open mind means a willingness to trust the equipment and not waste time guessing or deviating from the search path to pursue something seen or guessed at.

2) Is the searcher equipped to produce useful results? A battery operated AM-FM-SW-VHF receiver with a useful signal strength indicator and a directional antenna suitable for a walking search that receives fairly well at the highest relevant frequency is essential. See the Power-line Noise section for examples of what works for that type of source. Handheld SDR receivers are now available that can act as a portable spectrum analyzer, as well.

3) Does the searcher know how to direction-find? The type of power lines or potential sources in the area is irrelevant at this point. Finding the structure that contains the source is the only objective. Only by trusting your equipment and using it correctly to lead you to the source will the job get done with a minimum of wasted time and effort.

4) Has the searcher done enough listening and record keeping to have a good idea when the source is active, the best (highest?) frequency at which to listen to hear and track the source. Information includes:

- Signal strength

## Prospecting for RFI

By using several types of radios at the same time, you can characterize a wide area. For example, RFI professional KB4T uses the following radios when driving; the vehicle AM/FM radio tuned to 1710 kHz AM, an IC-7000 mobile HF transceiver tuned to 15 MHz AM (WWV), and an IC-2820 VHF receiver tuned to 121.500 MHz in AM mode. All three are operated unsquelched with the volume turned down so only a slight hiss is heard. A noise source will be very apparent on one or more of the radios when approached or passed.

## Hunting Noise with an SDR

Portable SDR receivers can be very good tools for locating noise sources and characterizing them, replacing the battery-powered AM radio. The article "Tracking RFI with an SDR One Source at a Time" by Alan Higbie, KØAV, in the March/April 2021 issue of the *National Contest Journal* (included in this chapter's downloadable supplemental material) describes the process. An example of using an SDRPlay for "site surveys" is described by Dave Cole, NK7Z at **www.nk7z.net/sdr-for-rfi-survey-p1**. In that example, a PC stores data over an extended period across spectrum extending from audio through 2 GHz. Other resources are available, including RFI snapshots, at **www.nk7z.net**.

Hams aren't the only ones with RF noise problems. Two extensive studies of RF noise mitigation were also conducted by the US Navy and the authors of these studies were all radio amateurs. "The Signal-to-Noise Enhancement Program" and "The Mitigation of Radio Noise and Interference from On-Site Sources at Radio Receiving Sites" are both available from the ARRL. Scroll to the bottom of **www.arrl.org/radio-frequency-interference-rfi** to the section "Naval Postgraduate School RFI Handbooks".

## Common Mistake — It's Everywhere, Joe Even Hears It Across Town!

RFI from a typical otherwise legal consumer device usually only propagates for a few hundred feet or less. However, the ARRL often receives reports of non-power line noise RFI covering an extraordinarily wide area. In this case – multiple hams hear a noise at opposite ends of a town, across a state wide area, or in some cases, even a multi-state region.

The fact of the matter is that RFI is a very common problem. And if you look hard enough, noise from a consumer devices can probably be heard in most suburban neighborhoods these days. Many of them sound alike, so much so that they can easily be mistaken for each other.

Conclusion: Don't rely on RFI reported by hams in other locations as being the same RFI at your location. Before concluding that the RFI covers a widespread area, always make sure that an RFI source is not local and nearby.

Note: While power-line noise at 80 or 40 meters can propagate for miles, it won't propagate much more than that. Most power-line noise sources can sound alike so beware. Power-line noise will not propagate across state or multi-state-wide regions. In this case, the ARRL recommends the use of signature analysis to determine which source or sources are contributing to an RFI problem before making unnecessary repairs. See the section on Power-Line Noise for more information on signature analysis. — *Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

- Highest frequency at which each source can be heard
- A simple description of each source's character
- Any other descriptive data
- Brief notes about weather conditions

If you can record the noise for a long period of time that shows the time as well as the noise, that will provide a lot of information about the source, as well.

5). Can it be decided what tools are best to locate the source? (Receiver, antenna, attenuator) Even if the right tools are in hand, mastery of them is essential. Make sure you know how to interpret the measurements or work with an experienced user to learn how.

### NOISE SOURCE SIGNATURES

Be wary of assuming too much about a source based on what the interference "sounds like" on a receiver or even "looks like" on an oscilloscope or spectrum analyzer. At the beginning of the search, "keep it simple" by not making too many assumptions about the nature of the source. Once the location of a source has been determined, then you can begin to narrow the search based on the source's "fingerprint" or signature.

Keep an open mind, be deliberate in your search, and don't act on assumptions about what a source is or isn't until you have exhausted the search techniques. Much time has been wasted in looking for sources of RFI because of assuming a location or type of source at the beginning.

### MULTIPLE NOISE SOURCES

Consider that the source may be more than a single piece of equipment! You might have power-line noise combined with switchmode power supply noise, for example. Trying to find the source based on the combination of noise signatures will be frustrating at best. Most suburban and urban locations have multiple noises active at any time. Survey the area to see if different sources are stronger in different areas.

Take careful notes about the nature and behavior of the source, then let your location-finding equipment lead you to each source in turn. It is often most productive to work on the strongest noise source first. Be prepared to discover there are multiple levels of noise sources — after dealing with the top-level source, you may find additional (and equally objectionable) sources remain. Be patient!

### VERIFY NOISE IS EXTERNAL TO THE RADIO

Whenever an unknown source of interference becomes an issue, you can begin the process of identifying the source by verifying that the problem is external to your radio. This advice might not sound very useful but it can save you a lot of wasted time. Start by removing the antenna connection. If the noise disappears, the source is external to your radio and you are ready to begin hunting for the noise source.

## 27.5.1 Locating Noise Sources Inside Your Home

Professional RFI investigators and the experiences of the ARRL RFI desk confirm that most RFI sources are ultimately found to be in the complainant's home. Furthermore, locating an in-house source of RFI is so simple that it makes sense to start an investigation by simply turning off your home's main circuit breaker while listening to the noise with a battery-powered portable radio.

Remember that battery-powered equipment may also be a noise source — turn off or disable battery-powered consumer devices, as well. If you have a UPS (uninterruptable power supply) it will continue to operate with

ac power removed. It may be necessary to actually disconnect the UPS battery to shut it completely down.

If the noise goes away, you know the source is in your residence. After resetting the breaker, you can further isolate the source by turning off individual breakers one at a time. Once you know the source circuit, you can then unplug devices on that circuit to find it.

CAUTION: *Do not attempt to remove cartridge fuses or operate exposed or open-type disconnects if it is possible to make physical contact with exposed electrical circuits.*

### 27.5.2 Locating Noise Sources Outside Your Home

It is often possible to locate a noise source outside your home with a minimum of equipment and effort. The following process will help you determine whether the noise is radiated directly to your equipment or conducted, most frequently by power lines or wiring which then radiate the noise signal themselves.

Because of Part 15's absolute emissions limits, most noise sources that are compliant with Part 15 are within a few hundred feet of the complainant's antenna. They are also often on the same power transformer secondary system as the complainant if the noise is conducted. This typically reduces the number of possible residences to relatively few.

If the noise source is not compliant with Part 15 limits, it may be blocks, or in some rare cases, even thousands of feet from your station. The ballasts of grow lights, for example, have been known to exceed the FCC limits by a considerable margin and have been heard for over ½ mile. Some Part 15 devices, battery chargers for electric scooters and wheelchairs, for example, are well-known for exceeding Part 15 absolute emissions limits on conducted noise.

Electrical noise sources in a home, such as an arcing thermostat or a noisy washing machine controller, can also be tracked down in the same way as noise from consumer electronic devices. Electrical noise from an incidental emitter, such as a power line, can propagate much farther than noise from an otherwise legal unintentional emitter.

The following procedure can be used to trace a noise source to a private home, town house, apartment, or condominium. The number of homes that could be host to a source generating noise could make searching house by house impractical. In such cases, use noise tracking techniques discussed in the following sections to narrow the search to a more reasonable area.

1) Verify that the noise is active before attempting to locate it. Don't forget this all-important first step. You cannot find the source when it's not present.

## Common Mistake — It's Not Me, I've Already Eliminated My House as the Source

Consumer devices are by far one of the most common sources of RFI. And once found, a surprisingly high percentage of them are actually in the complainant's home. For this reason, that we recommend that hams affected by noise open the main breaker to their residence while listening with a battery-powered radio. (See the text's caution about making sure battery-powered devices are off, as well.) If the noise goes away, you can further isolate the source by tripping the individual circuit breakers.

While all this sounds simple enough, many hams actually skip this step. Unplugging or turning off suspect sources is not the same as tripping the main breaker. Another mistake is to conclude that the source could not be in your home because you haven't bought or changed anything. Even though quiet when new, devices that fail or otherwise break down can become a source of RFI.

Conclusion: When it comes to consumer devices, do not assume that a noise source is not in your home until you open the main breaker. This is a simple and easy test to perform. Many hams have spent months – even years – searching for a noise that they could have easily found with simple breaker test. Why skip it? *— Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

## Common Mistake — Nothing In My Home Could Cause Noise Like That

One of the most common sources of RFI is the ubiquitous switching mode power supply. They are found in almost everything these days. Devices such as "wall warts," many light bulbs, computers, battery chargers, televisions and various other appliances all may and probably do include switchers capable of causing RFI. In addition, many other electronic devices have clocks and other oscillators that can cause RFI.

Despite this reality, it is surprising how many hams are convinced that the source of an RFI problem could not possibly be located in their home. They are often proven wrong.

Conclusion: Do not automatically that nothing in your home could cause an RFI problem. Almost every electronic device in a home can be suspect. Furthermore, a typical home these days can contain hundreds of potential RFI sources.*— Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

## Common Mistake — I Don't Have the Equipment

Most consumer devices actually meet the FCC emission limits so the RFI problem is usually limited to about 300 feet or less. They are also often in the complainant's residence, and if not, frequently in a home connected to the same power transformer secondary system as the complainant.

With this in mind, a simple portable (battery powered) shortwave radio capable of hearing the noise is all you typical need to find it. Opening the main breaker of your home will locate many of the problems. And if it's not in your home, it's likely in an adjacent or nearby residence. By collapsing or removing the antenna, adding a step attenuator, or reducing the RF gain of the locating receiver, you can often reduce the area in which you search for the source. Reducing the signal level to something at or below the receiver's AGC threshold (or turning AGC off) can often help.

An approach that often works is to find the loudest power pole. Next, look to see what houses are connected to that pole. And finally, if possible, hold the radio a short distance from the power meters at each house. Always be sure to minimize signal levels but do not make any adjustments when making comparisons between the different meters. If access to the power meters is not possible, you can use lawn lights or similar for this. The house with the highest noise level will be the one containing the source.

Please note that spectrum analyzers are not needed. In fact, in many cases, a spectrum analyzer can add to confusion, especially if there are other sources at other frequencies.

Conclusion: Finding noisy consumer devices is often easier than most people think. Furthermore, it does not require specialized equipment. A cheap battery powered shortwave radio will often do the job. *— Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

2) If possible, use a beam to record bearings to the noise before leaving your residence. Walk or drive through the neighborhood with particular emphasis in the direction of the noise, if known. Try to determine the rough geographic area over which the noise can be heard. If the geographic area over which you can hear the noise is confined to a radius of several hundred feet or less, or it diminishes quickly as you leave your neighborhood, this confirms you are most likely dealing with a Part 15 consumer device.

3) Since the noise will be strongest at an electrical device connected to the residence containing the source, you want to measure the noise at a device common to the exterior of all the potential homes. Suitable devices include electric meters, main service breakers (whether outside or in a utility room), front porch lights, electric lamp posts, outside air conditioner units, or doorbell buttons. Whatever radiator you choose, it should be accessible at each home. The device you select to test as the noise radiator will be referred to in these instructions as the "radiator." Using the same type of device as a test point at each home helps obtain consistent results.

4) You are now ready to compare the relative signal strengths at the radiator on each of the potential source residences. Use a detector suitable to receive the noise, typically a battery-powered receiver. Preferably, the receiver should have a variable RF gain control. An external step attenuator will also work if the antenna is external to the radio. If the antenna can be removed, a probe can also be made from a small piece of wire or paper clip to reduce the receiver's sensitivity. Start by holding the detector about two inches from the radiator at the residence where the noise source may be located. Turn the detector's RF gain control down to a point where you can just barely hear the noise. Alternately, increase the attenuation if using an external step attenuator. Record the RF gain or attenuator setting for each test. Because any wiring connected to a portable receiver becomes part of the receiver's antenna, including headphones, external battery, even the operator's hands and body, keep the configuration the same as you evaluate each potential source.

5) Proceed to the next residence. Again hold the detector approximately two inches from the radiator. (The detector should be placed at the same location at each residence, as much as is practical.) Since you had previously set the detector to just barely hear the noise at the residence having the interference problem, you can move on to the next residence if you do not hear the noise. Remember, in order for your detector to hear the noise at the next house, the noise level will have to be the same or higher than the previous location. If you need to increase the detector's sensitivity to be able to hear the noise, you are moving away from the noise source.

6) When you reach the next residence, if the level is lower or not heard, you're moving further from the source. Continue your search to residences in other directions or across the street. If the level is higher, then you're headed in the right direction. Be sure to turn the gain control down to the point of just barely hearing the noise as its strength increases.

7) Continue on to the next house, repeating the previous steps as necessary. The residence with the source will be the one with the strongest noise at the radiator.

Depending on the circumstances of a particular situation, it may be possible to first isolate the power pole to which the source residence is connected. Walk or drive along the power lines in the affected area while listening to the noise with a battery-powered radio. Continue to decrease the receiver's RF gain as the noise gets louder, thus reducing the area over which you can hear it. Finally, isolate the loudest pole by reducing the RF gain to a point at which you can hear it at only one pole. Once the pole has been isolated, look to see which houses are connected to its transformer. Typically this will reduce the number of potential residences to a very small number.

Be aware that not all power poles have a grounding conductor (a wire running down the side of the pole into the ground). This wire will carry currents from the entire section of the power system for that pole. A receiver held close to that wire will hear more noise than at poles without a ground wire. This may create a "false positive" with respect to homes fed from that pole — the actual noise source may be in any home connected to that section of the power system. Follow up by checking the power drop to the home and, if possible, at the meter before identifying that residence as the source of the noise. Noise on power lines can travel a long way and it is easy to be fooled by where it is heard.

CAUTION: *Always observe good safety practices! Only qualified people familiar with the hazards of working around energized electrical equipment should inspect power-line or other energized circuitry.*

When attempting to isolate the pole, it is often best to use the highest frequency at which you can hear the noise. Noise can exhibit peaks and nulls along a power line that are a function of its wavelength. Longer wavelengths can therefore make it difficult to pinpoint a particular point along a line. Furthermore, longer wavelength signals typically propagate further along power lines. You can often reduce your search area by simply increasing the frequency at which you look for the noise.

In some cases, tuning upward in frequency can also be used to attenuate noise. This can be especially helpful in cases where your receiver does not have an RF gain control. As mentioned previously, switchmode power supplies typically generate noise that exhibits a regular and repeating pattern of peaks and nulls across the spectrum. While a typical interval might be every 50 kHz or so, the noise will often start to diminish at the highest frequencies. The peaks in some cases might drift over time, but tuning to the highest frequency at which you can hear the noise will often attenuate it enough to help locate it. If the peak drifts however, be sure to keep your receiver set on the peak as you attempt to locate the source.

Under FCC rules, the involved utility is responsible for finding and correcting harmful interference that is being generated by its own equipment. In cases where a utility customer is using an appliance or device that generates noise, the operator of the device is

## Common Mistake — It Must Be The XYZ Company — They Were Just Here

Many hams might notice activity in their neighborhood by a cable, power or telephone company. Other variations include an installation of something electrical at an adjacent or nearby residence. Typical examples might include a swimming pool pump, broadband, satellite TV or an alarm system. So far, so good...

The problem, however, will become apparent a few days later when he or she turns on their radio. Interference now plagues the amateur bands! The ham may now erroneously conclude that the interference is a result of the activity he saw in his neighborhood several days prior. In some cases, the ham is so convinced of the source that they fail to take even the most rudimentary steps to confirm their suspicions. This often leads to significant delays in resolving their problem.

The reality in a typical suburban neighborhood is that there could easily be over a thousand devices in range of an amateur's antenna if those sources are all at the legal limit. This RFI environment is also constantly in transition as family members and nearby neighbors buy or turn on electronic devices and other appliances.

Conclusion: Do not automatically assume that you know what the source of an interference problem is based on activity that you've seen in the neighborhood. Always verify the source to the best extent possible.
*— Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

responsible for fixing it — even if the noise is conducted and radiated by the power company's power lines.

### 27.5.3 Approaching Your Neighbor

Once you identify the source residence and approach your neighbor, the importance of personal diplomacy simply cannot be overstated. The first contact regarding an RFI problem between a ham and a neighbor is often the most important; it is the start of all future relations between the parties. The way you react and behave when you first discuss the problem can set the tone for everything that follows. It is important, therefore, to use a diplomatic path from the very start. A successful outcome can depend upon it!

A self-help guide for the consumer published jointly by the ARRL and the Consumer Electronics Association (CEA) often proves helpful when discussing an interference problem with a neighbor. Entitled *What To Do if You Have an Electronic Interference Problem*, it may be printed and distributed freely. It is available on the ARRL website at **www.arrl.org/information-for-the-neighbors-of-hams** and also in the downloadable supplemental information accompanying this book. Be sure to download and print a copy for your neighbor before you approach him or her.

With the noise active and with a copy of the pamphlet handy, approach your neighbor with a radio in hand, preferably an ordinary AM broadcast or short-wave receiver. Let them hear it but not so loud that it will be offensive. Tell them this is the problem you are experiencing and you believe the source may be in their home. Don't suggest what you think the cause is. If you're wrong, it often makes matters worse. Give them the pamphlet and tell them it will only take a minute to determine whether the source is in their home. Most neighbors will agree to help find the source, and if they agree to turn off circuit breakers, it can be found very quickly. Start with the main breaker to verify you have the correct residence, then the individual breakers to find the circuit. The procedure then becomes the same as described for your own residence.

### 27.5.4 Radio Direction Finding

Radio direction finding (RDF) can be a highly effective method to locate an RFI source although it requires more specialized equipment than other methods. RDF techniques can be used to find both broadband and single-signal, narrowband noise sources. Professional interference investigators almost always use radio direction finding techniques to locate power-line noise sources. See the **Antennas** chapter for more information on direction finding antennas. The following recommendations are most effective in locating noise from a broadband source. For narrow-band, single-signal sources, regular RDF techniques are the most effective way to determine a source's location.

A good place to start, whenever possible, is at the affected station. Use an AM receiver, preferably one with a wide IF bandwidth. An RF gain control is particularly helpful but an outboard step attenuator can be a good substitute. If there is a directional beam capable of receiving the noise, use it on highest frequency band at which the noise can be heard using the antenna. If you can hear the noise at VHF or UHF, you'll typically want to use those frequencies for RDF.

Select a frequency at which no other stations or signals are present and the antenna can discern a directional peak in the noise. Rotate the beam as required to get a bearing on the noise, keeping the RF gain at a minimum. Repeat with a complete 360° sweep using the minimum RF gain possible to hear the noise in its loudest direction. Try to decrease the RF gain to a point at which the noise clearly comes from one and only one direction. You can simultaneously increase the AF gain as desired to hear the noise.

Distant sources, including power-line noise, are generally easier to RDF at HF than nearby sources. Whenever possible, it's almost always better to use VHF or UHF when in close proximity to a source. Tracking a source to a specific residence by RDF at HF is sometimes possible. Such factors as balance and geometry of a home's internal wiring, open switch circuits and distance, may cause the residence to appear somewhat as a point source.

If the search is being conducted while mobile or portable, VHF and UHF are typically the easiest and most practical antennas. Small handheld Yagi antennas for 2 meters and 440 MHz are readily available and can serve double duty when operating portable. Many handheld receivers can be configured to receive AM on the VHF bands. Be sure to check your manual for this feature. VHF Aircraft band or "Air band" receivers are also a popular choice since they receive AM signals.

Using RDF to locate an HF noise source while in motion presents significant challenges. Conducted emissions are typical from a consumer device or appliance. In this case, the emissions can be conducted outside the residence and on to the power line. The noise can then propagate along neighborhood distribution lines, which in turn acts as an antenna. The noise can often exhibit confusing peaks and nulls along the line, and if in the vicinity of a power line radiating it, RDF can be extremely difficult, if not impossible. Depending on the circumstances, you could literally be surrounded by the near field of an antenna! You would generally want to stay away from power lines and other potential radiators when searching at HF.

Antennas for HF RDF while walking typically include small loops and ferrite rod antennas. In some cases, a portable AM broadcast radio with a ferrite rod antenna can be used for direction finding. An HF dipole made from a pair of whip antennas may be able to be used to get an approximate bearing toward the noise. Mount the dipole about 12 feet above ground (remembering to watch out for overhead conductors!) and rotate to null out the noise. For all three types of antenna, there will be two nulls in opposite directions. Note the direction of the null. Repeat this procedure from another location then triangulate to determine the bearing to the noise.

# 27.6 Power-Line Noise

This chapter's section "Identifying RFI Source Types" describes power-line noise, its causes, and methods to identify it. Power-line noise is a unique problem in several respects. First and foremost, the offending source is never under your direct control. You can't just simply "turn it off" or unplug the offending device. Nor will the source be under the direct control of a neighbor or someone you are likely to know. In the case of power-line noise, the source is usually operated by a company, municipality, or in some cases, a cooperative. Furthermore, shutting down a power line is obviously not a practical option.

Another unique aspect of power-line noise is that it almost always involves a defect of some sort. The cure for power-line noise is to fix the defect. This is almost always a utility implemented repair and one over which you do not have any direct control.

FCC rules specify that that the operator of a device causing interference is responsible for fixing it. Whenever encountering a power-line noise problem, you will be dealing with a utility and won't have the option of applying a relatively simple technical solution to facilitate a cure, as you would if the device were located in your home. Utilities have a mixed record when it comes to dealing with power-line noise complaints. In some cases, a utility will have a budget, well-trained personnel, and equipment to quickly locate and address the problem. In other cases, however, the utility is simply unable to effectively deal with power-line noise complaints or even denies their equipment can cause RFI.

What does this mean for an amateur with a power-line noise complaint? Utilities can be of any size from large corporations to local cooperatives or city-owned systems. Regardless of the category in which your utility may fall, it must follow Part 15 of the FCC rules. Dealing with a company, coop or municipality, however, as opposed to a device in your home, or a nearby neighbor that you know personally, can present its own set of unique challenges. Multiple parties and individuals are often involved, including an RFI investigator, a line crew and associated management. In some cases, the utility may never have received an RFI complaint before yours.

### 27.6.1 Before Filing a Complaint

Obviously, before filing a complaint with your local utility, it is important to verify the problem as power-line noise as best as possible and verify that it is not caused by a problem with electrical equipment in your home. Other sources, such as lighting devices and motors, can mimic power-line noise, especially to an untrained ear. Don't overlook these important steps. Attempting to engage your utility in the resolution of an RFI problem can not only waste time but can be embarrassing if the source is right in your own home!

Utilities are not responsible for noise generated by customer-operated devices — *even if the noise is being radiated by the power lines.* They are responsible for fixing only that noise which is being generated by their equipment.

### 27.6.2 Filing a Complaint

Once you have verified the problem to be power-line noise (see this chapter's section on Identifying Power-line and Electrical Noise) and that it is not coming from a source in your home or a nearby residence, contact your utility's customer service department. In addition to your local phone book, customer service phone numbers are included on most power company websites.

**It is important to maintain a log during this part of the process.** Be sure to record any "help ticket" numbers that may be assigned to your complaint as well as names, dates and a brief description of each conversation you have with electric company personnel. If you identify specific equipment or power poles as a possible noise source, record the address and any identifying numbers on it.

Hopefully, your complaint will be addressed in a timely and professional manner. Once a noise source has been identified, it is up to the utility to repair it within a reasonable period. You and the utility may not agree on what constitutes a reasonable period, but attempt to be patient. If no action is taken after repeated requests, reporting the complaint to the ARRL and requesting assistance may be in order. (Before contacting the ARRL review The Cooperative Agreement, a section of this chapter.)

It is also important to cooperate with utility personnel and treat them with respect. Hostile and inappropriate behavior is almost always counter-productive in these situations. Remember, you want utility and other related personnel to help you — not avoid you. Even if the utility personnel working on your case seem unqualified, hostile behavior has historically never been a particularly good motivator in these situations. In fact, most protracted power-line noise cases reported to the ARRL began with an altercation in the early stages of the resolution process. In no case did it help or expedite correction of the problem.

### 27.6.3 Techniques for Locating Power-line Noise Sources

Radio direction finding (RDF) techniques typically offer the best and most efficient approach to locating most power-line noise sources. It is the primary method of choice used by professionals. While RDF is usually the most effective method, it also requires some specialized equipment, such as a hand-held beam antenna. Although specialized professional equipment is available for RDF, hams can also use readily available amateur and homebrew equipment successfully. The downloadable supplemental information for this *Handbook* includes some power-line noise locating equipment projects you can build. This includes a simple and easy to build RDFing antenna, an ultrasonic dish, and attenuators.

Although it is the utility's responsibility to locate a source of noise emanating from its equipment, many companies simply do not possess the necessary expertise or equipment to do so. As a practical matter, many hams have assisted their utility in locating noise sources. In some cases, this can help expedite a speedy resolution.

#### Common Mistake — It's Coming From That Pole!

RFI problems from consumer devices, especially below 30 MHz, frequently involve conducted emissions. The RF in this cases is generated by a consumer device in a home. It is then conducted by the house wiring, where it is radiated. In some cases, the RF can also be conducted to the service entrance of the home and out to a utility pole. In this case, the noise will peak at the pole and appear to be the source of the interference. It is not. The real source of the problem is in a residence connected to the pole.

Always verify that the actual source is not in a home connected to that pole. Frequently, the source residence will be connected to the power transformer secondary system on that pole. Also keep in mind that the hardware on a pole can also make for a better "antenna." This means that noise tends to peak at poles in general. Noise also tends to peak at about every half wavelength as you traverse along a power line. Be sure to use higher frequencies (i.e., shorter wavelengths) whenever possible.

Conclusion: Don't automatically assume that the source of an RFI problem is on a pole where the noise peaks. This is a common mistake made by many beginners!

*— Mike Gruber, W1MG (ARRL EMC Engineering,* **rfi@arrl.org**)

There is a significant caveat to this approach however. Should you mislead the power company into making unnecessary repairs, they will become frustrated. This expense and time will be added to their repair list. Do not make a guess or suggestions if you don't know what is causing the noise. While some power companies might know less about the locating process than the affected ham, indiscriminate replacement of hardware almost always makes the problem worse. Nonetheless, depending on your level of expertise and the specifics of your situation, you may be able to facilitate a speedy resolution by locating the RFI source for the utility.

### 27.6.4 Amateur Power-line Noise Locating Equipment

Additional information on the equipment, antennas, and techniques used to locate power line noise are also discussed in the *ARRL Antenna Book's* material on Direction Finding. Before discussing how to locate power-line noise sources, here are a few additional equipment guidelines.

***Receiver*** — You'll need a battery-operated portable radio capable of receiving VHF or UHF in the AM mode. Ideally, it should also be capable of receiving HF frequencies, especially if the interference is a problem at HF and not VHF. Some amateurs also use the aircraft band from 108 to 137 MHz. The lower frequencies of this band can sometimes enable an RFI investigator to hear the noise at greater distances than on 2 meters or 70 cm. An RF gain control is essential but an outboard step attenuator can be used as a substitute. A good S-meter is also required.

***Attenuator*** — Even if your receiver has an RF gain control, an additional outboard step attenuator can often be helpful. It can not only minimize the area of a noise search but also provide added range for the RF gain control. As with other RFI sources — you'll need to add more and more attenuation as you approach the source.

***VHF/UHF Antennas*** — You'll need a hand-held directional beam antenna. A popular professional noise-locating antenna is an eight-element Yagi tuned for 400 MHz. Since power-line noise is a broadband phenomenon, the exact frequency is not important. Either a 2 meter or 70 cm Yagi are capable of locating a power-line noise source on a specific power pole.

Although professional grade antennas can cost several hundred dollars, some hams can build their own for a lot less. See this book's downloadable supplemental information for the article, "Adapting a Three-Element Tape Measure Beam for Power-line Noise Hunting," by Jim Hanson, W1TRC. This low cost and easy to build antenna for locating power-line noise can be adapted for a variety of frequencies and receivers. Commercial 2 meter and 70 cm antennas for portable use are also suitable if a handle is added, such as a short length of PVC pipe.

Before using an antenna for power-line noise locating, determine its peak response frequency. Start by aiming the antenna at a known power-line noise source. Tune across its range and just beyond. Using minimum RF gain control, find its peak response. Label the antenna with this frequency using a piece of tape or marking pen. When using this antenna for noise locating, tune the receiver to this peak response frequency.

If you don't have a VHF or UHF receiver that can receive AM signals, see the downloadable supplemental content for the article, "A Simple TRF Receiver for Tracking RFI," by Rick Littlefield, K1BQT. It describes the combination of a simple 136 MHz beam and receiver for portable RFI tracking.

***HF Antennas*** — Depending on the circumstances of a particular case, a mobile HF whip such as a 7 or 14 MHz model can be helpful. Magnet-mount models are acceptable for temporary use. An RFI investigator can typically get within VHF range by observing the relative strength of the noise from different locations. Driving in a circle centered on the affected station will typically indicate the general direction in which the noise is strongest. As with beam antennas, determine the peak response frequency for best results.

***Ultrasonic Pinpointer*** — Although an ultrasonic pinpointer is not necessary to locate the pole or structure containing the source, some hams prefer to go one more step by finding the offending noise source on that structure. Guidelines for the use of an ultrasonic device are described later in this section.

Professional-grade ultrasonic locators are often beyond the budget of the average ham. Home brewing options however, can make a practical ultrasonic locator affordable in most situations — and make a great weekend project too. See the downloadable supplemental information accompanying this book for "A Home-made Ultrasonic Power Line Arc Detector" by Jim Hanson, W1TRC.

***Oscilloscope*** — A battery-powered portable oscilloscope is only required for signature analysis. See the next section, Signature or Fingerprint Method, for details.

***Thermal/Infrared Detectors and Corona Cameras*** — This equipment is not recommended for the sole purpose of locating power-line noise sources. It is rare that an RFI source is even detectable using infrared techniques. Although these are not useful tools for locating noise sources, many utilities still use them for such purposes with minimal or no results. Not surprisingly, ARRL experience has shown that these utilities are typically unable to resolve interference complaints in a timely fashion.

### 27.6.5 Signature or Fingerprint Method

Each sparking interference source exhibits a unique pattern. By comparing the characteristics between the patterns taken at the affected station with those observed in the field, it becomes possible to conclusively identify the offending source or sources from the many that one might encounter. It therefore isn't surprising that a pattern's unique characteristic is often called its "fingerprint" or "signature." See **Figure 27.8** for an example.

This is a very powerful technique and a real money saver for the utility. Even though there may be several different noise sources in the field, this method helps identify only those sources that are actually causing the interference problem. The utility need only correct the problem(s) matching the pattern of noise affecting your equipment.

You as a ham can use the signature method by observing the noise from your radio's audio output with an oscilloscope. Record the pattern by drawing it on a notepad or taking a photograph of the screen. Take the sketch or photograph with you as you hunt for the source and compare it to signatures you might observe in the field.

Professional interference-locating receivers, such as the Radar Engineers Model 243 shown in Figure 27.8, have a built in time-domain display and waveform memory similar to a digital oscilloscope. This is the preferred method used by professional interference investigators. These receivers provide the ability to switch between the patterns saved at the affected station and those from sources located in the field.

Once armed with the noise fingerprint taken at the affected station, you are ready to begin the hunt. If you have a directional beam, use it to obtain a bearing to the noise. If multiple sources are involved, you'll need to record the bearings to each one. Knowing how high in frequency a particular noise can be heard also provides a clue to its proximity. If the noise can be heard at 440 MHz, for example, the source will typically be within walking distance. If it diminishes beginning 75 or 40 meters, it can be up to several miles away.

Since each noise source will exhibit unique characteristics, you can now match this noise "signature" with one from the many sources you may encounter in the investigation. Compare such characteristics as the duration of each noise burst, pulse shape, and number of pulses. Be wary of assuming that all devices have similar signatures when arcing. The fingerprint of a particular piece of hardware arcing may be quite different even for the same device on another pole.

If you have a non-portable oscilloscope,

(A) (B)

**Figure 27.8 — The spectrum of an unknown noise source is shown on the display of a Model 243 RFI locating receiver (A) along with a typical noise receiving antenna (B). During the RFI investigation, noise signatures not matching this pattern can be ignored. Once the matching signature originally shown in A is found, the offending noise source has been located.**

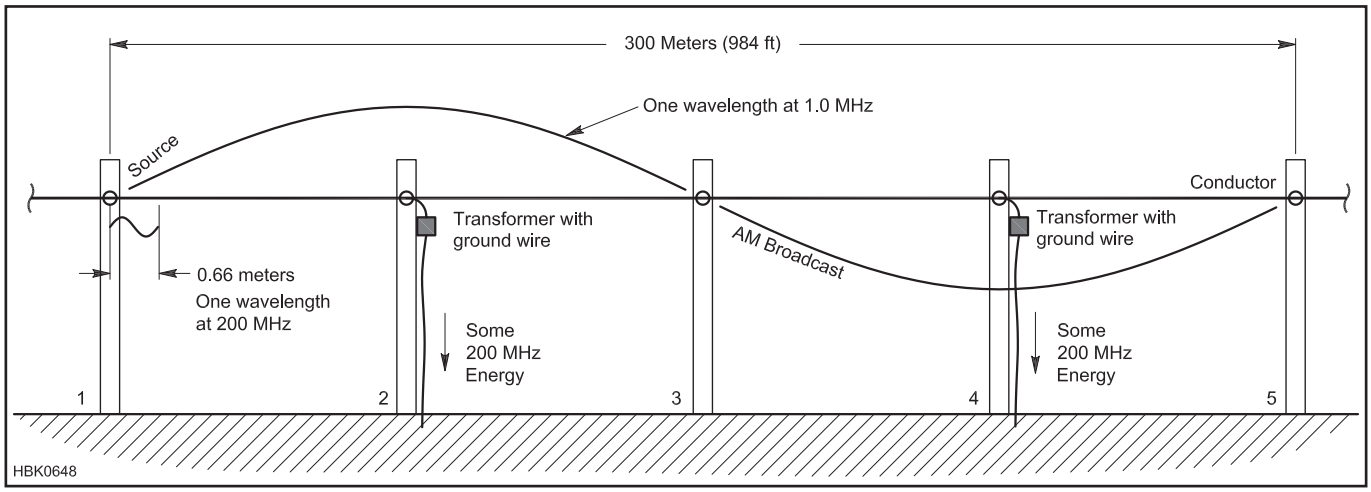

**Figure 27.9 — Listening for noise signals on a power distribution line at 1 MHz vs 200 MHz can result in identification of the wrong power pole as the noise source. (From Loftness, *AC Power Interference Handbook*)**

you may still be able to perform signature matching by using an audio recorder. Make a high quality recording of the noise source at your station and at each suspected noise source in the field, using the same receiver if possible. Replay the sounds for signature analysis.

## 27.6.6 Locating the Source's Power Pole or Structure

Start your search in front of the affected station. If you can hear the noise at VHF or UHF, begin with a handheld beam suitable for these frequencies. As discussed previously, the longer wavelengths associated with the AM broadcast band and even HF, can create misleading "hotspots" along a line when searching for a noise source as shown in **Figure 27.9**.

As a general rule, only use lower frequencies when you are too far away from the source to hear it at VHF or UHF. Generally work with the highest frequency at which the noise can be heard. As you approach the source, keep increasing the frequency to VHF or UHF, depending on your available antennas. Typically, 2 meters and 70 cm are both suitable for isolating a source down to the pole level.

If you do not have an initial bearing to the noise and are unable to hear it with your portable or mobile equipment, start traveling in a circular pattern around the affected station, block-by-block, street-by-street, until you find the noise pattern matching the one recorded at the affected station.

Once in range of the noise at VHF or UHF, start using a handheld beam. You're well on your way to locating the structure containing the source. In many cases, you can now continue your search on foot. *Again, maintain minimum RF gain to just barely hear the noise over a minimum area.* This is important step is crucial for success. If the RF gain is too high, it will be difficult to obtain accurate bearings with the beam.

Power-line noise will often be neither vertically nor horizontally polarized but somewhere in between. Be sure to rotate the beam's polarization for maximum noise response. Maintain this same polarization when comparing poles and other hardware.

## 27.6.7 Pinpointing the Source on a Pole or Structure

Once the source pole has been identified, the next step becomes pinpointing the offending hardware on that pole. A pair of binoculars

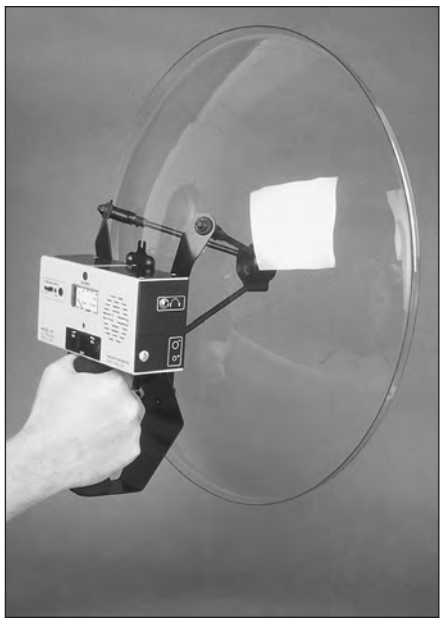

**Figure 27.10 — The clear plastic parabolic dish is an "ear" connected to an ultrasonic detector that lets utility personnel listen for the sound of arcs.**

**Figure 27.11 — The Radar Engineers Model 247 Hotstick Line Sniffer is an RF and ultrasonic locator. It is used by utility workers to pinpoint the exact piece of hardware causing a noise problem. Mounted on a hotstick, the sniffer is used from the ground or from a bucket.**

on a dark night may reveal visible signs of arcing and in some cases you may be able to see other evidence of the problem from the ground. These cases are rare. More than likely, a better approach will be required. Professional and utility interference investigators typically have two types of specialized equipment for this purpose:

- An ultrasonic dish or pinpointer. The RFI investigator, even if not a lineman, can pinpoint sources on the structure down to a component level from the ground using this instrument. See **Figure 27.10**.
- An investigator can instruct the lineman on the use of a hot stick-mounted device used to find the source. This method is restricted to only qualified utility personnel, typically from a bucket truck. See **Figure 27.11**.

Both methods are similar but hams only have one option — the ultrasonic pinpointer.

CAUTION — *Hot sticks and hot stick mounted devices are not for hams! Do not use them. Proper and safe use of a hot stick requires specialized training. In most localities, it is generally unlawful for anyone unqualified by a utility to come within 10 feet of an energized line or hardware. This includes hot sticks.*

Remember that it may be interesting to you to determine what piece of equipment is generating noise but it is the utility's job to positively complete the identification and then work on the equipment. Once you have identified the noise as coming from a particular location, be prepared to step back and let the professionals do their job.

#### ULTRASONIC PINPOINTER TIPS

An ultrasonic dish is the tool of choice for pinpointing the source of an arc from the ground. While no hot stick is required, an unobstructed direct line-of-sight path is required between the arc and the dish. This is not a suitable tool for locating the structure containing the source. It is only useful for pinpointing a source once its pole or structure has been determined.

Caveat: Corona discharge, while typically not a source of RF power-line noise, can and often is a significant source of ultrasonic sound. It can often be difficult to distinguish between the sound created by an arc and corona discharge. This can lead to mistakes when trying to pinpoint the source of an RFI problem with an ultrasonic device.

The key to success, just as with locating the structure, is using gain control effectively. Use minimum gain after initially detecting the noise. If the source appears to be at more than one location on the structure, reduce the gain. In part, this will eliminate any weaker noise signals from hardware not causing the problem.

### 27.6.8 Common Causes of Power-line Noise

The following are some of the more common power-line noise sources. They're listed in order from most common to least common. Note that some of the most common sources are not connected to a primary conductor. This in part is due to the care most utilities take to ensure sufficient primary conductor clearance from surrounding hardware. Note, too, that power transformers do not appear on this list:

- Loose staples on ground conductor
- Loose pole-top pin
- Ground conductor touching nearby hardware
- Corroded slack span insulators
- Guy wire touching neutral
- Loose hardware
- Bare tie wire used with insulated conductor
- Insulated tie wire on bare conductor
- Loose cross-arm braces
- Lightning arrestors

### 27.6.9 The Cooperative Agreement

While some cases of power-line noise are resolved in a timely fashion, the reality is that many cases can linger for an extended period of time. Many utilities simply do not have the expertise, equipment or motivation to properly address a power-line noise complaint. There are often no quick solutions. Patience can often be at a premium in these situations. Fortunately, the ARRL has a Cooperative Agreement with the FCC that can help. While the program is not a quick or easy solution, it does offer an opportunity and step-by-step course of action for relief. It emphasizes and provides for voluntary cooperation without FCC intervention.

Under the terms of the Cooperative Agreement, the ARRL provides technical help and information to utilities in order to help them resolve power-line noise complaints. It must be emphasized that the ARRL's role in this process is strictly a technical one — it is not in the enforcement business. In order to participate, complainants are required to treat utility personnel with respect, refrain from hostile behavior, and reasonably cooperate with any reasonable utility request. This includes making his or her station available for purposes of observing and recording noise signatures. The intent of the Cooperative Agreement is to solve as many cases as possible before they go to the FCC. In this way, the FCC's limited resources can be allocated where they are needed the most — enforcement.

As the first step in the process, the ARRL sends the utility a letter advising of pertinent Part 15 rules and offering assistance. The FCC then requires a 60-day waiting period before

the next step. If by the end of 60 days the utility has failed to demonstrate a good faith effort to correct the problem, the FCC then issues an advisory letter. This letter allows the utility another 60-day window to correct the problem.

A second FCC advisory letter, if necessary, is the next step. Typically, this letter provides another 20- or 30-day window for the utility to respond. If the problem still persists, a field investigation would follow. At the discretion of the Field Investigator, he or she may issue an FCC Citation or Notice of Apparent Liability (NAL). In the case of an NAL, a forfeiture or fine can result.

It is important to emphasize that the ARRL Cooperative Agreement Program does not offer a quick fix. There are several built-in waiting periods and a number of requirements that a ham must follow precisely. It does however provide a step-by-step and systematic course of action under the auspices of the FCC in cases where a utility does not comply with Part 15. Look for complete details, including how to file a complaint, in the ARRL's Power-line Noise FAQ web page at **www.arrl.org/power-line-noise-faq-page**.

# 27.7 Elements of RFI Control

## 27.7.1 Differential- and Common-Mode Signal Control

As shown in **Figure 27.12**, the path from source to victim almost always includes some conducting portion, such as wires or cables. RF energy can be conducted directly from source to victim, be conducted onto a wire or cable that acts as an antenna where it is radiated, or be picked up by a conductor connected to the victim that acts like an antenna. When the energy is traveling along the conducting portion of its path, it is important to understand whether it is a differential- or common-mode signal.

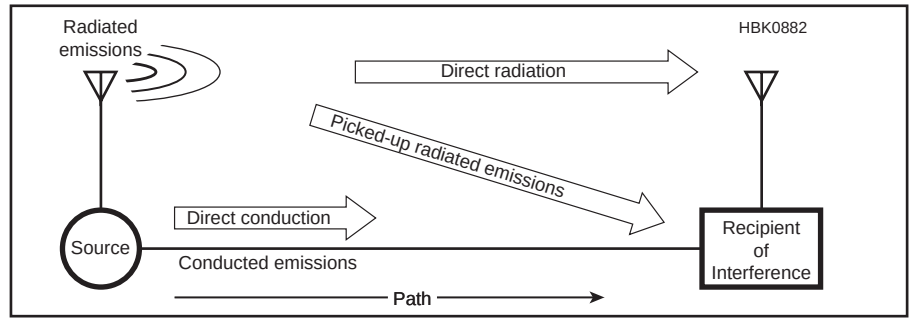

**Figure 27.12 — A block diagram showing every RFI problem involves three elements – a source, path and a victim. Fixing the problem requires removing one or more of them.**

Removing unwanted signals that cause RFI is different for each of these conduction modes. Differential-mode cures (a high-pass filter, low-pass filter, or a capacitor across the ac power line, for example) do not attenuate common-mode signals. Similarly, a common-mode choke will not affect interference resulting from a differential-mode signal.

It's relatively simple to build a differential-mode filter that passes desired signals and blocks unwanted signals with a high series impedance or presents a low-impedance to a signal return line or path. The return path for common-mode signals often involves earth ground, or even the chassis of equipment if it is large enough to form part of an antenna at the frequency of the RFI. A differential-mode filter is not part of this current path, so it can have no effect on common-mode RFI. Note that in practice, conducted emissions problems are more likely to be the result of common-mode than differential-mode signals.

In either case, an exposed shield surface is a potential antenna for RFI, either radiating or receiving unwanted energy, regardless of the shield's quality. In this way, a coaxial cable can act as an antenna for RFI if the victim device is unable to reject common-mode signals on the cable's shield. This is why it is important to connect cable shields in such a way that common-mode currents flowing on the shields are not allowed to enter the victim device. (See the section below on Cable Shield Connections.)

### RFI Email Reflector

A good source of information and help is the RFI email reflector maintained on the contesting.com website **lists.contesting.com/mailman/listinfo/RFI**). Simply subscribing in digest form provides a daily dose of RFI discussion. Before asking your question, however, be sure to check the reflector's searchable archives to see if your topic has been covered recently.

## 27.7.2 Shields and Filters

Breaking the path between source and victim is often an attractive option, especially if either is a consumer electronics device. Remember, the path will involve one or more of three possibilities — radiation, conduction, and inductive or capacitive coupling. Breaking the path of an RFI problem can require analysis and experimentation in some cases. Obviously you must know what the path is before you can break it. While the path may be readily apparent in some cases, more complex situations may not be so clear. Multiple attempts at finding a solution may be required.

### ENCLOSURE SHIELDING

Shielding can be used to control radiated emissions — that is, signals radiated by wiring inside the device — or to prevent radiated signals from being picked up by signal leads in cables or inside a piece of equipment. Shielding can also be used to reduce inductive or capacitive coupling, usually by acting as an intervening conductor between the source and victim.

Shields are used to set boundaries for radiated energy and to contain electric and magnetic fields. Thin conductive films, copper braid and sheet metal are the most common shield materials for the electric field (capacitive coupling), and for electromagnetic fields (radio waves). At RF, the small skin depth allows thin shields to be effective at these frequencies. Thicker shielding material is needed for magnetic field (inductive coupling) to minimize the voltage caused by

induced current. At audio frequencies and below, the higher skin depth of common shield materials is large enough (at 60 Hz, the skin depth for aluminum is 0.43 inches) that high-permeability materials such as steel or mu-metal (a nickel-iron alloy that exhibits high magnetic permeability) are required.

Maximum shield effectiveness usually requires solid sheet metal that completely encloses the source or susceptible circuitry or equipment. While electrically small holes generally do not affect shield effectiveness (fine-mesh screening makes good shielding at VHF and below, for example) seams can act as a slot antenna if they are a significant fraction of a wavelength long. In addition, mating surfaces between different parts of a shield must be conductive. To ensure conductivity, file or sand off paint or other nonconductive coatings on mating surfaces.

The effectiveness of a shield is determined by its ability to reflect or absorb the undesired energy. Reflection occurs at a shield's surface. In this case, the shield's effectiveness is independent of its thickness. Reflection is typically the dominant means of shielding for radio waves and capacitive coupling, but is ineffective against magnetic coupling. Most RFI shielding works, therefore, by reflection. Any good conductor will serve in this case, even thin plating.

Magnetic material is required when attempting to break a low-frequency inductive coupling path by shielding. A thick layer of high permeability material is ideal in this case. Although the near field of low frequency magnetic fields can extend for long distances, magnetic fields generally have their greatest effect at relatively short range. Simply increasing the distance between the source and victim may help avoid the expense and difficulty of implementing a shield.

Adding shielding may not be practical in many situations, especially with many consumer products, such as a television. Adding a shield to a cable can minimize capacitive coupling and RF pickup, but it has no effect on magnetic coupling. Replacing parallel-conductor cables (such as zip cord) with twisted-pair is quite effective against magnetic coupling and also reduces electromagnetic coupling.

Additional material on shielding may be found in Chapter 2 of Ott (see the References).

## FILTERS

Many RFI problems are caused by conducted emissions which leave the noise source as common-mode signals on wiring connected to the source. The noise may travel directly from the source to the victim or it might be radiated by the wiring and picked up by wiring connected to the victim. The same design or production problems that enable conducted emissions can also work in reverse, allowing the noise that has been picked up to be conducted into the victim where it causes the interference.

Filters and chokes can be very effective in dealing with a conducted emissions problem by blocking or suppressing the noise. Fortunately, filters and chokes are simple, economical and easy to try. As we'll see, use of common-mode chokes alone can often solve many RFI problems, especially at HF when common-mode current is more likely to be the culprit. In many cases, filters and chokes can also be applied externally to the victim device, avoiding the need to open an enclosure. Solving an RFI problem without having to alter a device's internal wiring is almost always preferable to the alternative.

A primary means of separating signals relies on their frequency difference. Filters offer little opposition to signals with certain frequencies while blocking or shunting others. Filters vary in attenuation characteristics, frequency characteristics and power-handling capabilities. The names given to various filters are based on their uses. (More information on filters may be found in the **Analog and Digital Filtering** chapter.)

***Low-pass filters*** pass frequencies below some cutoff frequency, while attenuating frequencies above that cutoff frequency. A typical low-pass filter curve is shown in **Figure 27.13A**. A schematic is shown in Figure 27.13B. These filters are can be difficult to construct properly so many hams choose to buy them. Many retail Amateur Radio stores that advertise in *QST* stock low-pass filters.

***High-pass filters*** pass frequencies above some cutoff frequency while attenuating frequencies below that cutoff frequency. A typical high-pass filter curve is shown in **Figure 27.14A**. Figure 27.14B shows a schematic of a typical high-pass filter. Again, it is best to buy one of the commercially available filters.

***Bypass capacitors*** can be used to cure differential-mode RFI problems by providing a low-impedance path for RF signals away from the affected lead or cable. A bypass capacitor is usually placed between a signal or power lead and the equipment chassis. If the bypass capacitor is attached to a shielded cable, the

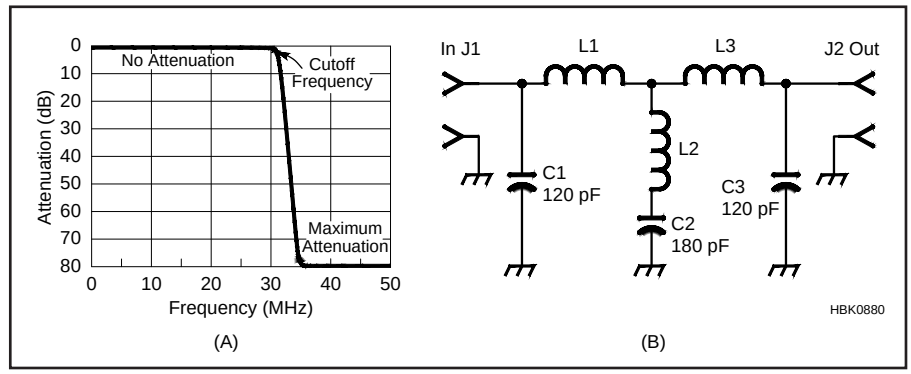

**Figure 27.13 — (A) An example of a low-pass filter's response curve. (B) A low-pass filter schematic for amateur transmitting use. Complete construction information appears in the Transmitters chapter of *The ARRL RFI Book*. A high-performance 1.8-54 MHz filter project can be found in the Analog and Digital Filtering chapter of this *Handbook*.**

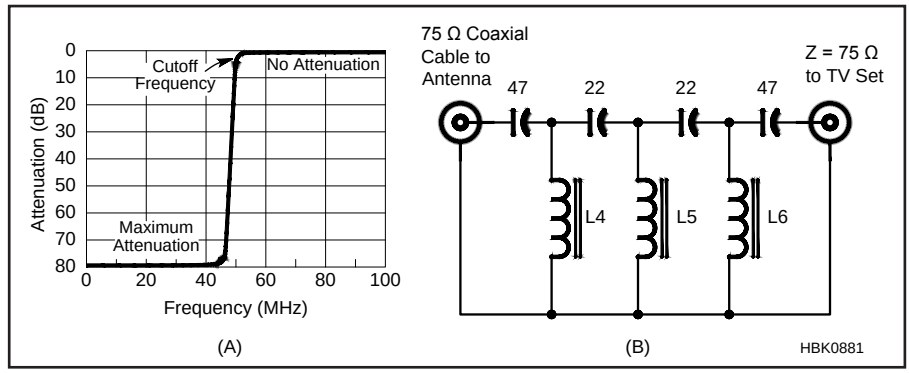

**Figure 27.14 — (A) An example of a high-pass filter's response curve. (B) A differential-mode high-pass filter for 75-Ω coaxial cable. It rejects HF signals picked up by a TV antenna or that leak into a cable-TV system. All capacitors are high-stability, low-loss, NP0 ceramic disc components. Values are in pF. The inductors are all #24 AWG enameled wire on T-44-0 toroid cores. L4 and L6 are each 12 turns (0.157 µH) and L5 is 11 turns (0.135 µH).**

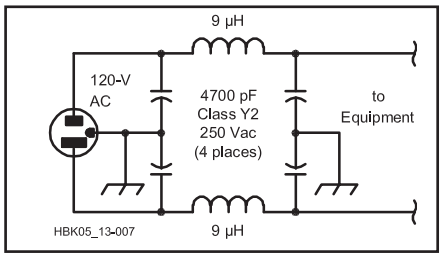

**Figure 27.15 — A "brute-force" ac-line filter. Note there is no filtering on the chassis ground connections. See the sidebar "Differential-Mode and Common-Mode Currents and RFI."**

shield should also be connected to the chassis. Bypass capacitors for HF signals are usually 0.01 µF, while VHF bypass capacitors are usually 0.001 µF. Leads of bypass capacitors should be kept short, particularly when dealing with VHF or UHF signals.

***AC-line filters***, sometimes called "brute-force" filters, are used to remove RF energy from ac power lines. A typical schematic is shown in **Figure 27.15**. Note that no filtering is performed on the ground or common connection. (See the Elements of RFI section for the definition for common-mode by utilities and ac power systems.)

Products from Corcom (**www.corcom.com**) and Delta Electronics (**www.deltaww.com**) are widely available and well documented on their websites. Morgan Manufacturing (**www.morganmfg.us**) sells stand-alone ac-line filters with ac plugs and sockets, such as the M-473 and M-475 series of AC Line Protectors. SMT EMI filters are now available for brush DC motors, as well, which are increasingly common in consumer appliances. See the *Microwaves & RF* article by Jeff Elliott in the References section for more information.

AC-line filters come in a wide variety of sizes, current ratings, and attenuation. In general, a filter must be physically larger to handle higher currents at lower frequencies. The Corcom 1VB1, a compact filter small enough to fit in the junction box for many low voltage lighting fixtures, provides good common-mode attenuation at MF and HF (only on the hot and neutral lines) and its 1 A at 250 V ac rating is sufficient for many LV lighting fixtures. In general, you will get more performance from a filter that is physically small if you choose the filter with the lowest current rating sufficient for your application. (Section 13.3 of Ott covers ac-line filters.)

The best location for an ac line filter is at the enclosure of the equipment. Filter modules can be bonded to the enclosure through the case of the filter (best) or via a bonding jumper to the enclosure. Bond the enclosure of the filter to the enclosure of the equipment by the shortest possible path. Many enclosures are painted which defeats the bonding of either a filter case, terminal, or solder lug. Clean the paint off the enclosure wherever a bonding connection is made.

Some commercial filters are built with an integral IEC power socket, and can replace a standard IEC connector if there is sufficient space behind the panel. (IEC is the International Electrotechnical Commission, an international standards organization that has created specifications for power plugs and sockets. See the **Safety** chapter for a drawing of an IEC connector.) The case of such a filter is bonded to the enclosure and interconnecting leads are shielded by the enclosure, optimizing its performance.

AC-line filters connected externally to equipment through a cord require extra attention. Any wiring between a filter and the equipment being filtered acts as an antenna and forms an inductive loop that degrades the performance of the filter. All such wiring should be as short as possible, and should be twisted. As described above, they do not apply filtering to the ground conductor which remains active for RFI. Wind several turns of the wiring on a ferrite core to block common-mode RF current on the ground conductor.

***AC-line capacitors*** — A capacitor between line and neutral or between line and ground at the noise source or at victim equipment can solve some RFI problems. ("Ground" in this sense is not "earth," it is the power system equipment ground — the green wire — at the equipment.) Power lines, cords, and cables are often subjected to short-duration spikes of very high voltage (4 kV). Ordinary capacitors are likely to fail when subjected to these voltages, and the failure could cause a fire. Only Type X1, X2, Y1 and Y2 capacitors should be used on power wiring. AC-rated capacitors can safely handle being placed across an ac line along with the typical voltage surges that occur from time to time. Type X1 and X2

## Differential-Mode and Common-Mode Currents and RFI

*Ed Hare, ARRL Lab Manager*

Most RFI problems involve a combination of differential-mode and common-mode signals or noise. (See the definition of these terms in the section Elements of RFI and Figures 27.3 and 27.16.) It is important to understand the difference between these two types of signals because generally, a filter designed to filter one type of signal will not be effective against the other type.

A common-mode filter is designed to not affect the differential-mode signals inside of the wiring being filtered. The result is that a common-mode choke would not attenuate any differential-mode noise carried by the wires being filtered. As another example, a differential-mode filter does not usually filter the ground lead in a 3-wire ac cord or cable (see Figure 27.15), so any common-mode signals or noise present on the ground conductor of the ac wiring would be coupled directly through the filter.

In many cases, a noisy device creates both differential-mode and common-mode currents, due to various imbalances in the device and the wiring it is connected to. A susceptible device experiencing interference from a nearby transmitter can be the result of both common-mode and differential-mode signals being picked up on its wiring. Imbalance in ac or signal wiring usually results in both types of signals being created and coupled into and out of devices. For this reason, in many cases, both common-mode and differential-mode filtering may be required.

If an amateur decides on filtering the ac line supplying equipment belonging to a neighbor, it is often best to resolve that problem as quickly and efficiently as possible. Experimenting to find out which type of filter is needed often leads to frustration on the part of the neighbor, who may quickly lose confidence in the ham's ability to resolve the problem. For this reason, it is usually advisable to install both common-mode and differential-mode filtering on a neighbor's device as shown in **Figure 27.A1**, resolving the interference that is present and making future interference less likely.

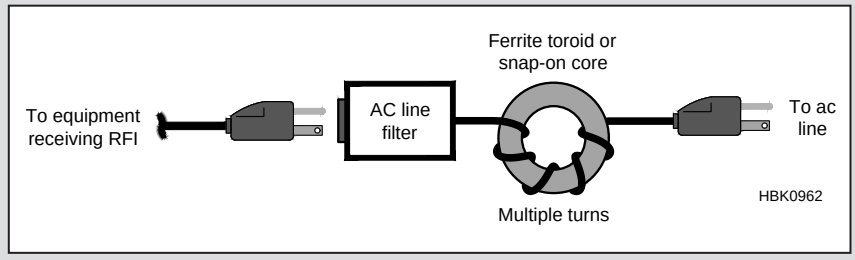

**Figure 27.A1 — An ac line filter and a ferrite RF choke combined in the ac line to the affected equipment block both differential- and common-mode current. The line filter can be a standalone model with plugs and receptacles or a module in a grounded metal enclosure. The ferrite mix should be type 31 (for HF) or type 43 (for middle HF through VHF). Either a toroid or clamp-on core can be used if multiple turns can be wound on the core to create sufficient choking impedance.**

capacitors are rated for use between line and neutral, and are available in values between 0.1 µF and 1 µF. Type X2 capacitors are tested to withstand 2.5 kV, type X1 capacitors are tested to 4 kV. Type Y1 and Y2 capacitors are rated for use between line and ground; Y1 capacitors are impulse tested to 8 kV; Type Y2 to 5 kV. Note that 4700 pF is the largest value permitted to be used between line and ground — larger values can result in excessive leakage currents.

## CABLE SHIELD CONNECTIONS

In this chapter's prior discussion of common-mode and differential-mode signals, the need for proper connection of cable shields was introduced. Improperly connected shields on audio, RF, and data cables are an important source of radiated and conducted emissions. In addition, they provide a path into equipment for common-mode RF that has been picked up on a cable shield as common-mode current. Either way, an improperly connected shield is a likely cause of RFI.

**Figure 27.16** describes the basic reasoning as to how cable shields should be connected. This is a very simplified overview to illustrate the basic concepts. Figure 27.16A shows a metal enclosure and an internal circuit, usually on a PC board. In the circuit itself, there is a common connection that could be a ground plane or point-to-point wiring or traces. Either way, there is some small impedance between any two points in the circuit's ground system.

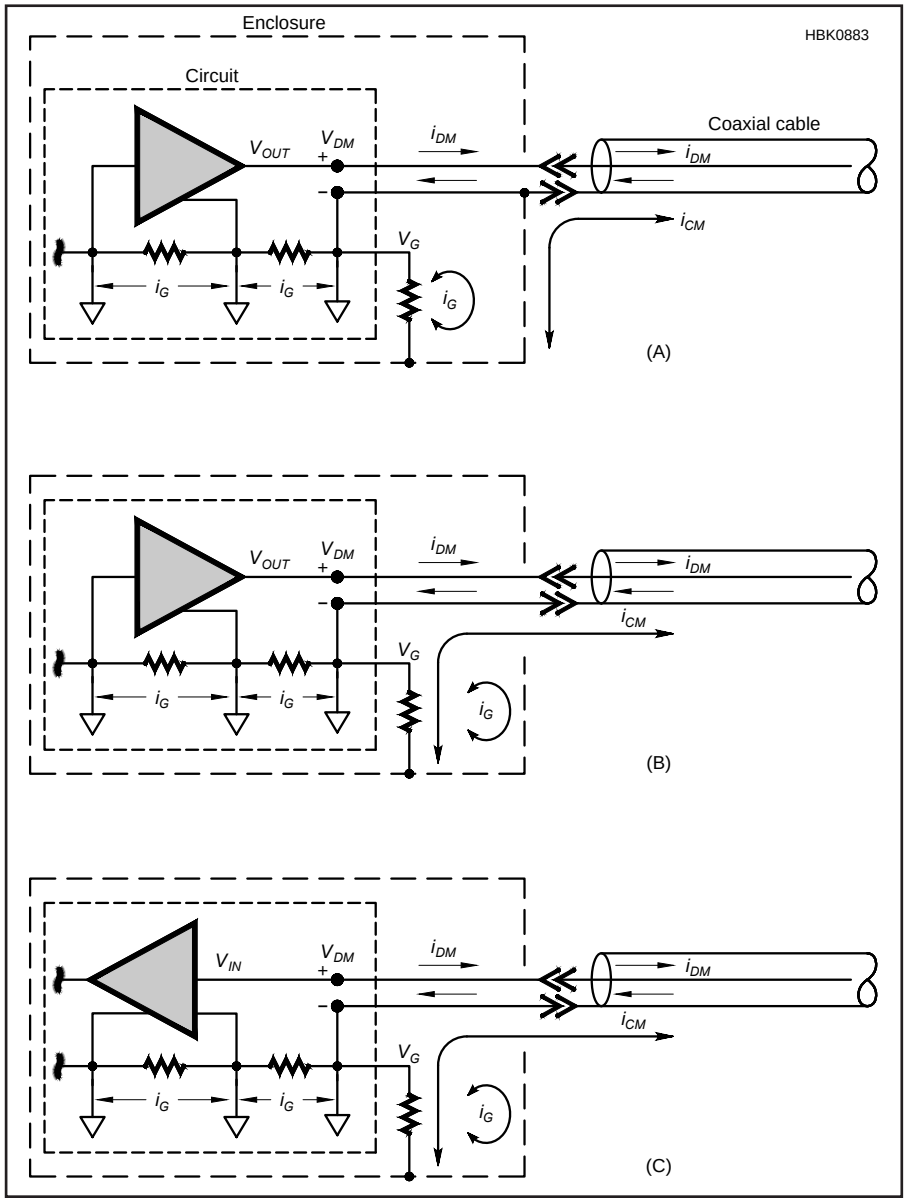

**Figure 27.16 — Properly (A) and improperly (B,C) connected shields showing undesired paths for common-mode current into and out of equipment. Improperly connected shields create an ingress and egress path for RF common-mode current. See the text for discussion.**

This is shown by the resistor symbols. Current flowing in the ground system is shown as $i_G$. The usual practice is to connect the ground system to the enclosure (chassis ground) through a wire or hardware. That, too, has some impedance, shown as a resistor.

The actual voltage applied to the cable connection, $V_{DM}$, is not equal to $V_{OUT}$. The ground currents flowing through the ground system impedances create small voltages. So does the ground current flowing through the connection between the circuit ground system and the enclosure. All of these voltages combine to create $V_G$, which then combines with the amplifier output voltage, $V_{OUT}$, to create $V_{DM}$.

Outside the enclosure, a coaxial cable is terminated in an RF connector, such as a PL-259, BNC, Type N, or even a shielded, metal phono plug. The differential-mode signal currents inside the cable (shown as $i_{DM}$) flow on the cable's center conductor and the *inside* of the cable shield. If a signal is picked up by the cable the resulting common-mode current (shown as $i_{CM}$) flows on the *outside* of the cable shield. Due to the skin effect, the inside and outside of the cable shield are independent conductors for RF currents.

On the inside of the mating connector (such as an SO-239) a cable or wire pair connect the $i_{DM}$ currents to the circuit. In Figure 27.16A, the center conductor in the cable is connected to some kind of amplifier output ($V_{OUT}$) and the enclosure-connected part of the connector to the circuit's common or ground terminal. If the connector and shield are attached properly, there is no path between the circuit's differential-mode common terminal and the outside, common-mode surface of the cable shield. Similarly, whatever current $i_{DM}$ is flowing inside the cable, it cannot flow to the outside of the cable where it would become common-mode current and radiate an unwanted signal — a radiated emission.

Figure 27.16B shows what happens when the shield connection goes through the enclosure and is connected directly to the inner circuit ground system. The common-mode current path is now open to $i_G$ that flows in the connection from the circuit ground system to

### Warning: Bypassing Speaker Leads

Older amateur literature might suggest connecting a 0.01-µF capacitor across an amplifier's speaker output terminals to cure RFI from common mode signals on speaker cables. Don't do this! Doing so can cause some modern solid-state amplifiers to break into a destructive, full-power, sometimes ultrasonic oscillation if they are connected to a highly capacitive load. Use common-mode chokes and twisted-pair speaker cables instead.

**Figure 27.17 — A common-mode RF choke wound on a toroid core is shown at top left. Several styles of ferrite cores for common-mode chokes are also shown.**

the enclosure. This allows noise and signals from the circuit to escape the enclosure as a radiated emission. The path is also open for $i_{CM}$ to flow in the enclosure connection and add to the voltage that makes up $V_G$. Depending on the ground system impedance, some of $i_{CM}$ can add to $i_G$, as well. This allows external noise and signals to get into the circuit's ground system and disrupt its operation.

Figure 27.16C illustrates the situation when the differential-mode signal is an input to the circuit. Noise and signals on the circuit ground system can still escape the enclosure. In addition, the common-mode current $i_{CM}$ combines with $i_G$ which modifies $V_G$ and $V_{IN}$. This can easily cause a lot of problems if the circuit is a receiver front end or other sensitive function.

Figure 27.3D showed a similar situation with two wires inside a shield. This is common for data or control connections where there might be several data lines and a dedicated signal return or signal ground circuit that is separate from the overall shield. Treat the signal return circuit as an independent circuit and do not connect it to the enclosure. Most shielded data cables have separate signal ground and shield connections. Only the shield should connect to the enclosure.

Not connecting the shield at all breaks the path for the desired differential-mode current on the inside of the shield. This forces it to find another return path, often through ground systems or power wiring. The gap in the shield creates an antenna similar to a magnetic loop that not only radiates the differential-mode signal but allows the undesired common-mode current to combine with the differential-mode signals. The whole system acts as if it were unshielded.

The need to connect the shields of cables to a shielding enclosure is clear whether they are coaxial cables, shielded twisted-pair, or multiconductor data cables. If the shield connection penetrates the enclosure and is connected directly to the circuit's ground system, both radiated emissions and incoming RFI are the likely result. In addition, the unintended current path can affect the impedance of the connection to the cable as discussed in the material on common-mode chokes later in this section and in the **Transmission Lines** chapter. It is possible to devise alternate connections, such as for transceiver microphone cables, but RF filtering or chokes and careful circuit ground system design and construction are required.

## 27.7.3 Common-Mode Chokes

Common-mode chokes on ferrite cores are the most effective answer to RFI from a common-mode signal. Differential-mode filters are *not* effective against common-mode signals. (AC-line filters usually only perform differential-mode filtering as described in the preceding section.) Common-mode chokes work differently, but equally well, with coaxial cable and paired conductors. (Additional material on common-mode chokes is found in sections 3.5 and 3.6 of Ott.)

The most common form of common-mode choke is multiple turns of cable wound on a ferrite toroid core as shown in **Figure 27.17**. The following explanation applies to chokes wound on rods as well as toroids, but avoid rod cores since they may couple to nearby circuits at HF. At HF, toroid cores are recommended — beads and clamp-on ferrite cores are usually adequate.

Most of the time, a common-mode signal on a coaxial cable or a shielded, multi-wire cable is a current flowing on the outside of the cable's shield. By wrapping the cable around a magnetic core the current creates a flux in the core, creating a high impedance in series with the outside of the shield. (An impedance of a few hundred to several thousand ohms are required for an effective choke.) The impedance then blocks or reduces the common-mode current. Because equal-and-opposite fields are coupled to the core from each of the differential-mode currents, the common-mode choke has no effect on differential-mode signals inside the cable.

When the cable consists of two-wire, unshielded conductors such as zip cord or twisted-pair, the equal-and-opposite differential currents each create a magnetic flux in the core. The equal-and-opposite fluxes cancel each other and the differential-mode signal experiences zero net effect. To common-mode signals, however, the choke appears as a high impedance in series with the signal: the higher the impedance, the lower the common-mode current.

It is important to note that common-mode currents on a transmission line will result in radiation of a signal from the feed line. (See the sidebar for an explanation of balanced vs unbalanced transmission lines.) The radiated signal can then cause RFI in nearby circuits. This is most common when using coaxial cable as a feed line to a balanced load, such as the dipole in the sidebar. Reducing common-mode current with a common-mode choke at the antenna feed point and where the feed line enters the residence can help reduce RFI caused by signals radiated from the feed line's shield.

Common-mode noise is also picked up by feed lines. If it is allowed to flow into the

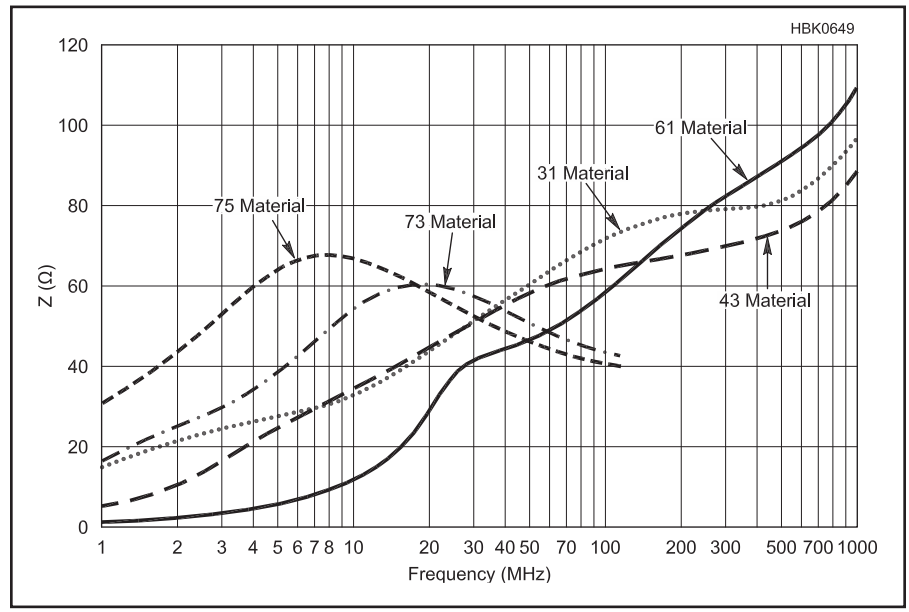

**Figure 27.18 — Impedance vs. frequency plots for "101" size ferrite beads illustrate the effect of various ferrite materials across different frequency ranges. A 3.50 mm × 1.30 mm × 6.00 mm bead (Fair-Rite 301 size) was used for the above curve for material comparison, however all materials are not available in all shapes and sizes. Type 73 material is only available in smaller cores, type 31 is only available in larger cores, and type 75 is currently only available as a toroid core. [Graph courtesy of the Fair-Rite Corporation]**

station, it can also be converted to differential-mode signals at connectors and by coupling to other cables and wiring in the station. Chokes can block this current and eliminate this source of received noise and unwanted signals which can contribute to the noise level considerably.

Common-mode chokes using ferrite cores are discussed at length in the **RF Techniques** and **Transmission Lines** chapters. They block common-mode RF current by adding a large value of resistive impedance in series with the common-mode circuit. The choke actually behaves as a parallel-self-resonant circuit that includes the winding inductance and stray capacitance along with the resistance of the core material at that frequency. (The electrical characteristics of ferrite at RF are discussed in the **RF Techniques** chapter.)

The self-resonance of a conductor passing once through most ferrite cores (considered to be one turn) used for suppression is in the range of 150 MHz, and this is where a core simply clamped around a cable will be effective. To obtain good suppression in the range of 1-50 MHz, we must wind multiple turns through the ferrite core to lower the resonant frequency. Common-mode chokes are typically wound on toroid cores with a 1-inch or greater inside diameter or a split-core clamp-on core.

**Figure 27.18** is a combined graph of the impedance of single turns through a ferrite bead of different mixes. It gives an idea of the range of ferrites that are available. By using the right material and the right number of turns through the core, choke impedance can be optimized for resistance and for the frequency range desired. Resistive impedance is desired to avoid interacting with the conductor's reactance at the frequency of use. The right material to use is specified for "suppression" over the frequency range required. (Fair-Rite mixes #31, #43, #44, and #61 are of the most use to amateurs.) This means the core's impedance is primarily resistive in that range. Chokes wound on these cores have a very low Q (because they are dissipating energy instead of storing it) so the choke's bandwidth can be as much as an octave. Chokes can be designed to work over different frequency ranges – placing chokes optimized for different ranges in series works over the combined frequency range.

Type 31 material is a good all-purpose material for HF and low-VHF applications, especially at low HF frequencies. Type 43 is widely used for HF through VHF and UHF. The **Component Data and References** chapter includes a table of ferrite materials and characteristics. This discussion only touches on the basic characteristics of ferrite-core common-mode chokes as they apply to dealing with RFI.

## Warning: Surplus Ferrite Cores

Don't use a core to make a common-mode choke if you don't know what type of material it is made of. Such cores may not be effective in the frequency range you are working with. This may lead to the erroneous conclusion that a common-mode choke doesn't work when a core with the correct material would have done the job.

## Feed Line Radiation — The Difference Between Balanced and Unbalanced Transmission Lines

The physical differences between balanced and unbalanced feed lines are obvious. Balanced lines are parallel-type transmission lines, such as ladder line or twin lead. The two conductors that make up a balanced line run side-by-side, separated by an insulating material (plastic, air, whatever). Unbalanced lines, on the other hand, are coaxial-type feed lines. One of the conductors (the shield) completely surrounds the other (the center).

In an ideal world, both types of transmission lines would deliver RF power to the load (typically your antenna) without radiating any energy along the way. It is important to understand, however, that both types of transmission lines require a balanced condition in order to accomplish this feat. That is, the currents in each conductor must be equal in magnitude, but opposite in polarity.

The classic definition of a balanced transmission line tells us that both conductors must be symmetrical (same length and separation distance) relative to a common reference point, usually ground. It's fairly easy to imagine the equal and opposite currents flowing through this type of feeder. When such a condition occurs, the fields generated by the currents cancel each other-hence, no radiation. An imbalance occurs when one of the conductors carries more current than the other. This additional "imbalance current" causes the feed line to radiate.

Things are a bit different when we consider a coaxial cable. Instead of its being a symmetrical line, one of its conductors (usually the shield), is grounded. In addition, the currents flowing in the coax are confined to the outside portion of the center conductor and the inside portion of the shield.

When a balanced load, such as a resonant dipole antenna, is connected to unbalanced coax, the outside of the shield can act as an electrical third conductor (see **Figure 27.A**). This phantom third conductor can provide an alternate path for the imbalance current to flow. Whether the small amount of stray radiation that occurs is important or not is subject to debate. In fact, one of the purposes of a balun (a contraction of balanced to unbalanced) is to reduce or eliminate imbalance current flowing on the outside of the shield. See the **Transmission Lines** chapter of this book for more information on baluns.

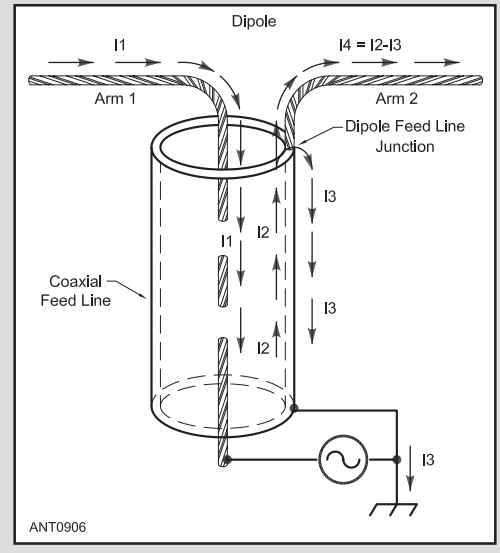

**Fig 27.A — Various current paths are present at the feed point of a balanced dipole fed with unbalanced coaxial cable. The diameter of the coax is exaggerated to show the currents clearly.**

# 27.8 Troubleshooting RFI

Troubleshooting an RFI problem is a multi-step process, and all steps are equally important. First you must determine the type(s) of noise source(s) that are involved. Next, diagnose the problem by locating the noise source and the means by which it creates the noise. The final step is to identify the path by which the noise or signals reach the victim device. Only then can you cure the problem by breaking the path from source to victim.

Each step in troubleshooting an RFI problem involves asking and answering several questions: Is the problem caused by harmonics, fundamental overload, conducted emissions, radiated emissions or a combination of all of these factors? Should it be fixed with a low-pass filter, high-pass filter, common-mode chokes or ac-line filter? How about shielding, isolation transformers, a different ground or antenna configuration? By the time you finish with these questions, the possibilities could number in the millions. You probably will not see your exact problem and cure listed in this book or any other. You must not only diagnose the problem but find a cure as well!

Now that you have learned some RFI fundamentals, you can work on specific technical solutions. A systematic approach will identify the problem and suggest a cure. Most RFI problems can be solved in this way by the application of standard techniques. The following sections suggest specific approaches for different types of common interference problems. This advice is based on the experience of the ARRL RFI Desk, but is not guaranteed to provide a solution to your particular problem. Armed with your RFI knowledge, a kit of filters and tools, your local TC and a determination to solve the problem, it is time to begin. You should also get a copy of the *ARRL RFI Book*. It's comprehensive and picks up where this chapter leaves off.

### 27.8.1 General RFI Troubleshooting Guidelines

Before diving into the problem, take a step back and consider some of these "pre-troubleshooting steps."

***Is It Really EMI?*** — Before trying to solve a suspected case of EMI, verify that the symptoms actually result from external causes. A variety of equipment malfunctions or external noise can look like interference.

***Is It Your Station?*** — "Your" EMI problem might be caused by another ham or a radio transmitter of another radio service, such as a local CB or police transmitter. If it appears that your station is involved, operate your station on each band, mode and power level that you use. Note all conditions that produce interference. If no transmissions produce the problem, your station *may* not be the cause. (Although some contributing factor may have been missing in the test.) Have your neighbor keep notes of when and how the interference appears: what time of day, what station, what other appliances were in use, what was the weather? You should do the same whenever you operate. If you can readily reproduce the problem with your station, you can start to troubleshoot the problem.

***Take One Away*** — Can you remove the source or victim entirely? The best cure for an RFI problem is often removing the source of the noise. If the source is something broken, for example, the usual solution is to repair it. Power-line noise and an arcing electric fence usually fall into this category. If a switchmode power supply is radiating noise, replace it with a linear supply. Victim devices can sometimes be replaced with a more robust piece of equipment, as well.

***Look Around*** — Aside from the brain, the eyes are a troubleshooter's best tool. Installation defects contribute to many RFI problems. Look for loose connections, shield breaks in a cable-TV installation or corroded contacts in a telephone installation. Have these fixed these first. Look for wiring connected to the victim equipment that might be long enough to be resonant on one or more amateur bands. If so, a common-mode choke may be an easy cure. Ideally you'll generally want place the choke as close to the victim device as practical. If this placement proves too difficult or additional suppression is required, chokes placed at the middle of the wiring may help break up resonances. These are just a few of the possible deficiencies in a home installation.

***At Your Station*** — Make sure that your own station and consumer equipment are clean. This cuts the size of a possible interference problem from your station in half! Once this is done, you won't need to diagnose or troubleshoot your station later. Also, any cures successful at your house may work at your neighbor's as well. If you do have problems in your own home, continue through the troubleshooting steps and specific cures and take care of your own problem first.

***Simplify the Problem*** — Don't tackle a complex system — such as a telephone system in which there are two lines running to 14 rooms — all at once. You could spend the rest of your life running in circles and never find the true cause of the problem.

There's a better way. In our hypothetical telephone system, first locate the telephone jack closest to the telephone service entrance. Disconnect the lines to more remote jacks and connect one RFI-resistant telephone at the remaining jack. (Old-style rotary-dial phones are often quite immune to RF.) If the interference remains, try cures until the problem is solved, then start adding lines and equipment back one at a time, fixing the problems as you go along. If you are lucky, you will solve all of the problems in one pass. If not, at least you can point to one piece of equipment as the source of the problem.

***Multiple Causes*** — Many RFI problems have multiple causes. These are usually the ones that give new RFI troubleshooters the most trouble. For example, consider a TVI problem caused by the combination of harmonics from the transmitter due to an arc in the transmitting antenna, an overloaded TV preamplifier, fundamental overload generat-

#### Dummy Detectives

One particularly useful troubleshooting tool for determining where RFI is entering a victim device is called a "dummy" – a short test cable that can be inserted in a signal path. The dummy's cable shield is connected on each end of the cable but the center conductor is not connected. The dummy will allow common-mode current to flow on the shield, but will not pass a differential-mode signal. This technique was devised by Bill Whitlocak of Jensen Transformers.

Dummies are quite useful in identifying where RFI is being introduced in a signal path. If the interference goes away when the dummy is inserted, the RFI is being introduced upstream of the dummy. If the interference is common-mode, it will still be present when the dummy is inserted upstream of the victim equipment that is detecting it because the dummy's shield passes common-mode noise to the victim.

An F connector dummy is easily made with two F plugs installed on a short length of coax. A double-receptacle F "barrel" adaptor can be attached to one of the plugs to create an extension cable. At one or both of the plugs, the center conductor is snipped flush with the shield so that it does not make contact with the mating connector.

Dummies made with RCA and 1/8-in connectors (mono and stereo) are also useful for the same purpose in home entertainment systems and other consumer electronics. Use high-quality connectors, such as those made by Switchcraft and Neutrik, and use good shielded cable that fits the connector, such as RG-174 subminiature coax. Cut the center conductor of the coaxial cable so that it does not make contact with the connector pins.

ing harmonics in the TV tuner, induced and conducted RF on the ac-power connections, and a common-mode signal picked up on the shield of the TV's coaxial feed line. You would never find a cure for this multiple-cause problem by trying only one cure at a time.

In this case, the solution requires that all of the cures be present at the same time. When troubleshooting, if you try a cure, leave it in place even if it doesn't solve the problem. When you add a cure that finally solves the problem entirely, start removing the "temporary" attempts one at a time. If the interference returns, you know that there were multiple causes.

***Take Notes*** — In the process of troubleshooting an RFI problem, it's easy to lose track of what remedies were applied, to what equipment, and in what order. Configurations of equipment can change rapidly when you're experimenting. To minimize the chances of going around in circles or getting confused, take lots of notes as you proceed. Sketches and drawings can be very useful. When you do find the cause of a problem and a cure for it, be sure to write all that down so you can refer to it in the future.

***RFI Survival Kit*** — **Table 27.1** is a list of the material needed to troubleshoot and solve most RFI problems. Having all of these materials in one container, such as a small tackle or craft box, makes the troubleshooting process go a lot smoother.

## 27.8.2 Transmitters

We start with transmitters not because most interference comes from transmitters, but because your station transmitter is under your direct control. Many of the troubleshooting steps in other parts of this chapter assume that your transmitter is "clean" (free of unwanted RF output).

Start by looking for patterns in the interference. Problems that occur only on harmonics of a fundamental signal usually indicate the transmitter is the source of the interference. Harmonics can also be generated in nearby semiconductors, such as an unpowered VHF receiver left connected to an antenna, rectifiers in a rotator control box, or a corroded connection in a tower guy wire. Harmonics can also be generated in the front-end components of the TV or radio experiencing interference.

If HF transmitter spurs at VHF are causing interference, a low-pass filter at the transmitter output will usually cure the problem. If an amplifier is used, be sure it is adjusted properly and not mistuned. If a filter at the transmitter is insufficient either the amplifier or transmitter may need repair or something else may be creating the harmonics. Transmitting filters are generally designed for 50 Ω input and output impedances, so install any filters on the input side of an antenna tuner, if one is used. Install a low-pass filter as your first step in any interference problem that involves another radio service at VHF or higher frequencies.

Interference from non-harmonic spurious emissions is extremely rare in commercial radios. Any such problem indicates a malfunction that should be repaired.

## 27.8.3 Television Interference (TVI)

Digital TV has somewhat better immunity than the obsolete analog system but for both formats, clear reception requires a strong signal at the TV antenna-input connector so the receiver must be in what is known as a *strong-signal area*.

TVI to a TV receiver (or a video monitor) normally has one of the following causes:

- Spurious signals within the TV channel coming from your transmitter or station.
- The TV set may be overloaded by your transmitter's fundamental signal.

**Table 27.1**
**RFI Survival Kit**

| *Quantity* | *Item* |

*Miscellaneous:*
- Hand tools, assorted screwdrivers, wire cutters, pliers
- Hookup wire
- Electrical tape
- Soldering iron and solder (use with caution!)
- Assorted lengths 75-Ω coaxial cable with connectors
- Spare F connectors, male, and crimping tool
- F-connector female-female "barrel"
- Clip leads
- Notebook and pencil
- Portable multimeter

## "Keeping It Simple"

Filters and chokes are the number one weapons of choice for many RFI problems whether the device is the source or the victim. They are relatively inexpensive, easy to install, and do not require permanently modifying the device.

***Common-mode choke*** — Making a common-mode choke is simple. Select the type of core and ferrite material for the frequency range of the interference. (Type 31 is a good HF/low-VHF material, type #43 from 5 MHz through VHF) Wrap several turns of the cable or wire pairs around the toroid. Six to 8 turns is a good start at 10-30 MHz and 10 to 15 turns from 1.8 to 7 MHz. (Ten to 15 turns is probably the practical limit for most cables.) Ferrite clamp-on split cores and beads that slide over the cable or wire are not as effective as toroid-core chokes at HF but are the right solution at VHF and higher frequencies. For a clamp-on core, the cable doesn't even need to be disconnected from its end. Use type 31 or type 43 material at VHF, type 61 at UHF. At 50 MHz, use two turns through type 31 or 43 cores.

***"Brute-Force" ac-line filters*** — RF signals often enter and exit a device via an ac power connection. "Brute-force" ac-line filters are simple and easy to install. Most ac filters only provide differential-mode suppression as described in the text. It is essential to use a filter rated to handle the device's required current.

**General installation guidelines for using chokes and filters**

1. If you have a brute-force ac-line filter, put one on the device or power cord. If RFI persists, add a common-mode choke to the power cord at the device.
2. Simplify the problem by removing cables one at a time until you no longer detect RFI. Start with cables longer than 1/10th-wavelength at the highest frequency of concern. If the equipment can't operate without a particular cable, add common-mode chokes at the affected or source device.
3. Add a common-mode choke to the last cable removed and verify its effect on the RFI. Some cables may require several chokes in difficult cases.
4. Begin reconnecting cables one at a time. If RFI reappears, add a common-mode choke to that cable. Repeat for each cable.
5. Once the RFI goes away, remove the common-mode chokes you added one at a time. If the RFI does not return, you do not need to reinstall the choke. If the RFI returns after removing a choke, reinstall it. Keep only those chokes required to fix the problem.

• Signals within the TV channel from some source other than your station, such as electrical noise, an overloaded mast-mounted TV preamplifier or a transmitter in another service.

• The TV set might be defective or misadjusted, making it look like there is an interference problem.

• One or more connecting cables is loose or defective. Be sure cables are of good-quality and that connectors are installed properly, especially older crimp-type F connectors.

All of these problems are made potentially more severe because TV receiving equipment is hooked up to *two* antenna systems: (1) the incoming antenna or cable feed line and (2) the ac power line and interconnecting cables. These two antenna systems can couple significant levels of fundamental or harmonic energy into the TV set or video display! The *TVI Troubleshooting Flowchart* in **Figure 27.19** is a good starting point.

The problem could also be caused by direct pickup of the transmitted signal by an unshielded TV or device connected to the TV.

Certain types of television receivers and video monitors are reported to cause broadband RF interference *to* amateur signals — large-screen plasma display models were at one time reported to be the most frequent offender — and this may be difficult to cure due to the nature of the display technology. Fortunately, less-expensive, more power-efficient, and RF-quieter LCD technology has displaced plasma technology for current models.

The manufacturer of the TV or video equipment can sometimes help with an interference problem. The Consumer Electronics Association (CEA) can also help you contact equipment manufacturers. Contact them directly for assistance in locating help at **www.ce.org**.

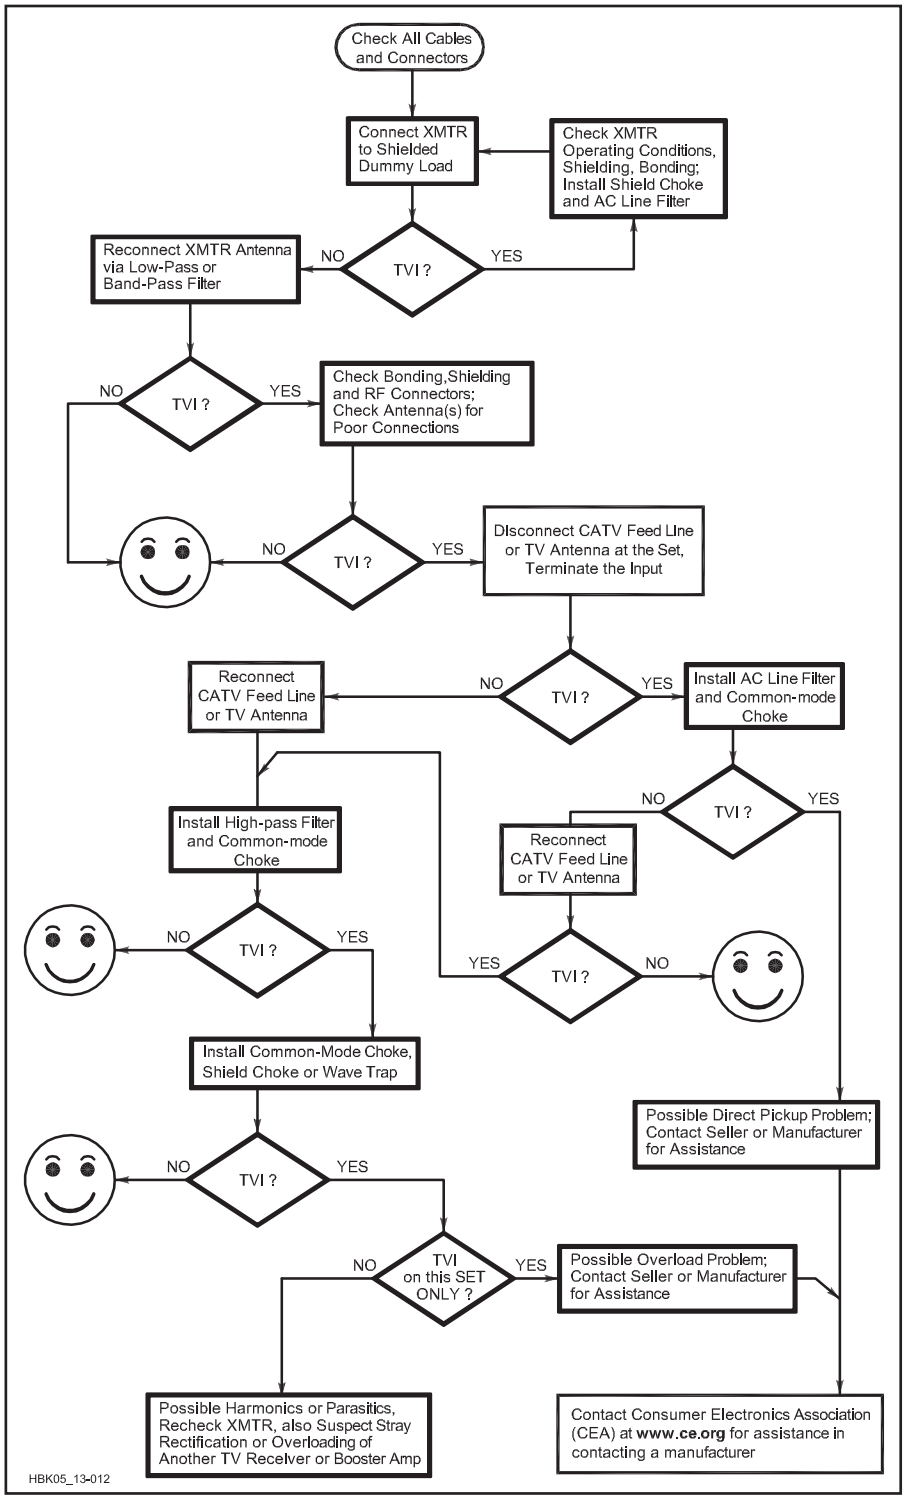

**Figure 27.19 — TVI troubleshooting flowchart.**

## COMMON SOURCES OF TVI

***HF transmitters*** — A nearby HF transmitter is most likely to cause fundamental overload. This is usually indicated by interference to all channels, or at least all VHF channels. To cure fundamental overload from an HF transmitter to an antenna-connected TV, install a high-pass filter directly at the TV set's antenna input. (Do not use a high-pass filter on a cable-TV input because the HF range is used for data and other system signals.)

A strong HF signal can also result in a strong common-mode signal on the TV's feed line. A common-mode choke will block signals on the outside of the feed line shield, leaving the desired signals inside the feed line unaffected. **Figure 27.20** shows how a common-mode choke is constructed for a coaxial feed line. The same choke can be applied

**Figure 27.20 — To eliminate HF and VHF signals on the outside of a coaxial cable, use an 1- to 2-inch OD toroid core and wind as many turns of the cable on the core as practical.**

to audio, control, and power cables, as well, to prevent RFI caused by common-mode ingress via these non-RF paths.

These filters and chokes can probably cure most cases of TVI! **Figure 27.21** shows a "bulletproof" installation for both over-the-air and cable TV receivers. If one of these methods doesn't cure the problem, the problem is likely direct pickup in which a signal is received by the TV set's circuitry without any conducting path being required. In that case, don't try to fix it yourself — it is a problem for the TV manufacturer.

High-pass filters *should not* be used in a cable TV feed line (Figure 27.21A) with two-way cable devices such as cable modems, set-top boxes, and newer two-way CableCARD-equipped TVs. The high-pass filter may prevent the device from communicating via the cable network's upstream signal path.

***VHF Transmitters*** —Most TV tuners are not very selective and a strong VHF or UHF signal, including those from nearby FM and TV transmitters, can overload the tuner easily, particularly when receiving VHF or UHF broadcasts over the air and not via a cable or satellite system. In this case, a notch or stop-band filter at the TV can help by attenuating the fundamental signal that overloads the TV tuner. Channel Plus (**www.solidsignal.com**), PAR Electronics (**www.parelectronics.com**), and Scannermaster (**www.scannermaster.com**) sell notch filters. A common-mode choke may also be necessary if the TV is responding to the common-mode fundamental signal present on the TV's feed line. Note that most TV broadcasts are now in the UHF spectrum, regardless of what channel number they use in their identification. You can find the actual channel used by a TV station at **transition.fcc.gov/dtv/markets** and **www.fcc.gov/media/engineering/dtvmaps** provides coverage maps based on Zip code.

If the VHF transmitter is generating a harmonic or other spurious emission causing RFI, a transmission line stub filter may be a good solution. The stub can be designed to remove a signal at the transmitter. If the transmitter's fundamental signal is overloading the receiver, a notch filter stub can also be applied at the receiver. See the **Transmission Lines** chapter for more information about these filters.

***TV Preamplifiers*** — Preamplifiers are only needed in weak-signal areas and they often cause trouble, particularly when used unnecessarily in strong-signal areas. They are subject to the same overload problems as TVs and when located on the antenna mast it can be difficult to install the appropriate cures. You may need to install a high-pass or notch filter at the input of the preamplifier, as well as a common-mode choke on the input, output and power-supply wiring (if separate) to effect a complete cure. All filters, connections, and chokes must be weatherproofed. A common-mode choke will reduce RF current on the feed line's shield.

For a common-mode feed line choke, use two 1-inch long type 43 clamp-on ferrite cores if VHF signals are causing the interference and type 61 material for UHF. HF choke design is discussed in the section on Common-Mode Chokes.

***Spurious Emissions*** — You are responsible for spurious emissions produced by your station. If your station is generating any interfering spurious signals, the problem must be cured there. Start by analyzing which TV channels are affected. A TV Channel Chart showing the relationship of the amateur allocations and their harmonics to over-the-air and cable channels is provided in this book's downloadable supplemental material. Each channel is 6 MHz wide. If the interference is only on channels that are multiples of your transmitting frequency, you probably have interference caused by harmonics of your transmitted signal. Harmonics from commercial transceivers, however, are quite rare. As mentioned earlier, significant harmonics from such equipment probably indicates a failure that needs to be repaired.

It is not certain that these harmonics are coming from your station, however. Harmonics can be generated by overloaded preamplifiers or tuner input circuits. Harmonics can also be generated like IMD products by nonlinear junctions near your station transmitter or very near the TV receiver antenna. (See the section on Intermodulation Distortion.) If your transmitter and station check "clean" — check to see if you have interference on a TV set in your own home — then you must look elsewhere for the source of the harmonics.

An inexpensive SDR receiver is a good way to see if spurious emissions of any sort — not necessarily just harmonics — are present. Several *QST* vendors sell complete SDR packages and SDR projects are available, as well. An online survey of SDR receivers, including portable models, is available on-

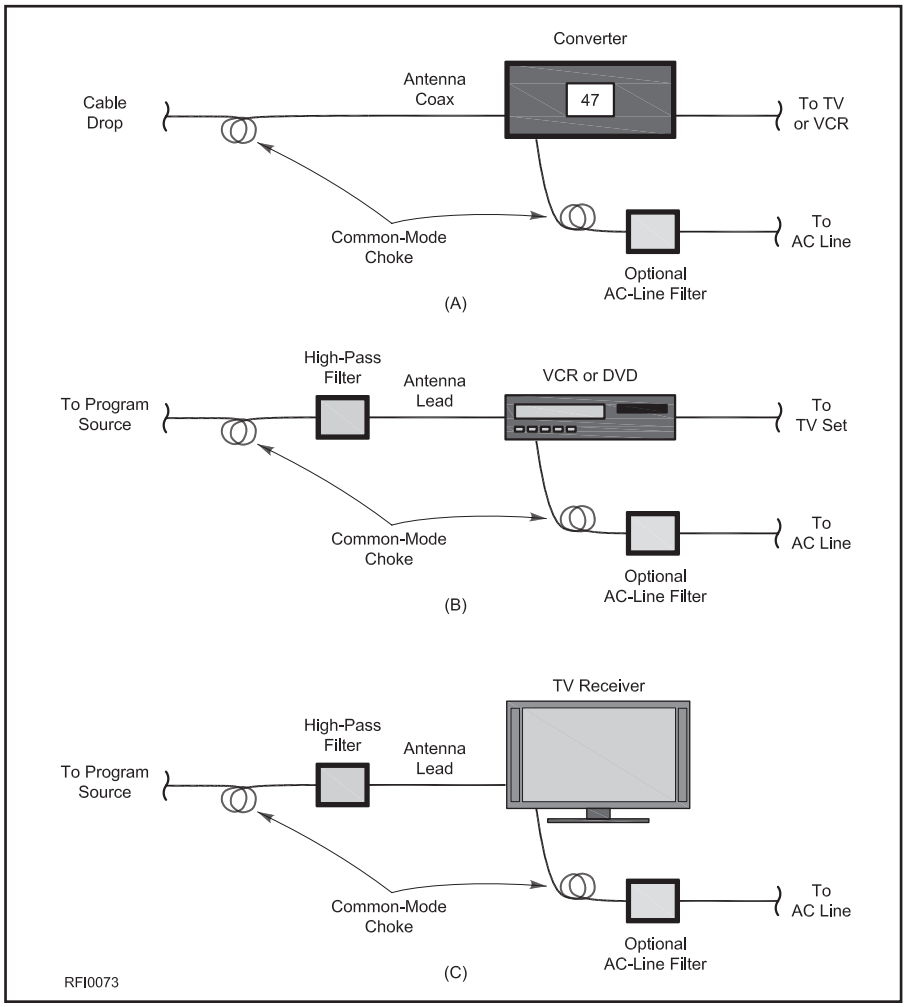

**Figure 27.21 — Installing common-mode chokes and high-pass filters will cure most fundamental overload interference from HF sources. Apply common-mode chokes in the ac power cord before adding ac-line filters. This technique does not address direct pickup or spurious emission problems.**

line at **www.rtl-sdr.com/roundup-software-defined-radios**.

***Electrical Noise*** — Digital TV signals are fairly resistant to electrical noise, but in extreme cases can cause the picture to freeze or fail to be displayed as discussed in the following section on Digital TV Receivers.

On an AM receiver (including SSB or CW receivers), electrical noise usually sounds like a buzz, sometimes changing in intensity as the arc or spark sputters a bit. If you have a problem with electrical noise, refer to the section on Electrical Noise.

### DIGITAL TV (DTV) RECEIVERS

Nearly all over-the-air TV broadcasters in the US, with the exception of low-power TV stations and translators, are using the DTV (digital TV) format. Digital TV signals can operate with much lower signal-to-noise ratios, but are still susceptible to interference.

Interference to digital TV signals from amateur signals — narrowband interference, for instance, a CW carrier — to a 6 MHz-wide digital TV signal generally has two effects. If the interfering signal is strong enough, it will cause degraded *modulation error ratio* (MER) and degraded *bit error rate* (BER) in the digital video signal. If the amplitude of the interference is sufficient, the digital receiver's *forward error correction* (FEC) circuitry will be unable to fix the broken bits, and the digital video signal will "crash." (See the **Digital Modes** chapter for more information on coding and error correction in digital protocols.)

TV viewers watching any of the multiple video streams that may be contained within the digital video signal won't see any problems in the picture (or hear anything wrong in the sound), until the so-called "crash point" is reached. At that point, the picture will begin to show intermittent "tiling" (the picture breaking up into small squares) or blocking (freezing) in the image. As the amplitude of the interfering signal increases perhaps another 0.5 dB to 1 dB, the crash point or "digital cliff" is reached, and the picture and sound are gone! As you can see, there is a tiny window between receiving a perfect picture and receiving no picture. The same effect is produced by signal fading and may be difficult to distinguish from RFI.

Interference to the digital signal does not make its presence known through visual or audible artifacts such as streaks, lines, or tearing in the picture, or garbled audio. This means that a viewer experiencing interference may not be able to identify its source, but troubleshooting interference may also become more difficult. Nevertheless, the more robust digital modulation is often less susceptible to interference from narrowband amateur signals. A clue to the source of the interference is that interference caused by an amateur signal will occur in sync with the amateur's transmissions while other types of interference will have no correlation.

The techniques for curing interference between amateur and digital TV signals are largely the same as they were for analog TV. Fundamental overload generally responds well to filters in the antenna or RF inputs. Interference caused by spurious emissions from the amateur station can be eliminated by filtering at the amateur transmitter. Common-mode problems in which RF signals are conducted into the television receiver's circuitry by external audio, video, and power cables are no more or less likely than for analog TV sets and can be addressed as described elsewhere in this chapter.

### ANALOG TV RECEIVERS

Even though over-the-air TV broadcasting largely switched to a digital format in 2009, many analog TV receivers are still in use for cable TV, satellite TV, with converter boxes for digital broadcast signals, and for displaying video from DVDs and other video sources. Older VCR and DVD players may also include an analog TV tuner to receive analog TV signals.

Interference to video displays and monitors that do not receive RF signals from an antenna or RF modulator should be assumed to be common-mode interference or direct pickup. The same applies to interference to a TV set displaying video signals (not through the antenna input). Interference that is present only on the audio is probably a case of common-mode RFI. (See the Stereos and Home Entertainment Systems section of this chapter.)

## 27.8.4 Cable TV

Cable TV has generally benefited Amateur Radio with respect to TVI. The cable system delivers a strong, consistent signal to the TV receiver, reducing susceptibility to interference from amateur signals. It is also a shielded system so an external signal shouldn't be able to cause interference. Most cable companies are responsible about keeping signal leakage (*egress*) and *ingress* — the opposite of leakage — under control, but problems do happen. Cable companies are not responsible for direct pickup or common-mode interference problems, but are responsible for leakage, ingress, and any noise radiated by common-mode currents from their equipment.

Cable companies are able to take advantage of something known as frequency reuse. That is, all radio frequencies higher than 5 MHz are used to transmit TV signals. The latter is possible because the cables and components used to transport signals to and from paying subscribers comprise what is known as a closed network. In other words, a cable company can use frequencies inside of its cables that may be used for entirely different purposes in the over-the-air environment. As long as the shielding integrity of the cable network is maintained, the cable company's signals won't interfere with over-the-air services, and vice-versa.

The reality is that the shielding integrity of a cable network *is* sometimes compromised, perhaps because of a loose or damaged connector, a cracked cable shield, rodent damage, poorly shielded customer premises equipment (CPE) such as cable-ready TVs and

### Common Mistake — It's the Cable System

The cable company is often incorrectly blamed for causing interference that is actually generated by consumer devices. Remember that all the individual circuit grounds in your home are bonded at the service entrance panel. The National Electrical Code also requires the cable TV ground to be bonded to this same ground system.

When you now consider that most RFI problems, especially at HF, involve conducted emissions, it's easy to see what can happen. Conducted emissions from a consumer device can propagate along ground conductors and wind up on the shield of the cable TV coax. The cable (and possibly other components of the cable TV system) can then radiate the noise.

Ron Hranac, NØIVN, also adds the following from an industry point of view:

"A key point that needs to be emphasized related to this topic is that in many cases wideband noise from consumer devices that is being coupled to and radiated from the cable TV network is often assumed to be leaking cable modem digital signals. The cable company channelizes its digital signals (downstream channel bandwidths are 6 MHz, and upstream channel bandwidths are typically either 3.2 MHz or 6.4 MHz). The cable company generally does not use upstream frequencies below about 15 MHz for cable modem data transmission, although there might be a narrowband data carrier from set-top boxes in the roughly 8 MHz to 12 MHz range. Cable modem upstream signals are generally found in the 20 MHz to 42 MHz range, sometimes as low as 15 MHz or so. The cable company does not transmit signals in the diplex filter cutoff region of about 42 MHz to 50 MHz, nor does it transmit signals below about the previously mentioned 8 MHz or so."

Conclusion: Don't automatically assume that the cable TV system is the cause of an RFI problem just because it is radiating the noise. — *Mike Gruber, W1MG (ARRL EMC Engineering, rfi@arrl.org)*

DVD and Blu-Ray players, and problems that may happen when someone tries to steal cable service! §76.605(a)(12) of the FCC Rules defines the maximum allowable signal leakage (*egress*) field strength at specified measurement distances, and §76.613 covers harmful interference. FCC Rules also mandate that cable operators "…shall provide for a program of regular monitoring for signal leakage by substantially covering the plant every three months," and leaks greater than 20 microvolts per meter (μV/m) at a 10 ft. measurement distance repaired in a reasonable period of time. As well, an annual "snapshot" of leakage performance must be characterized via a flyover measurement of the cable system, or a ground-based measurement of 75% of the network.

## CABLE TV FREQUENCY USAGE

A typical modern North American cable network is designed to use frequencies in the 5 to 1002 MHz spectrum. Signals that travel from the cable company to the subscriber occupy frequencies from just above 50 MHz to as high as 1002 MHz range (this is the downstream or forward spectrum), and signals that travel from the subscriber to the cable company are carried in the 5 to as high as 42 MHz range, known as the upstream or return spectrum. The downstream is divided into 6 MHz-wide channel slots, which carry 64- or 256-QAM digitally modulated signals used for digital video, high-speed data, and telephone services. (Analog cable service has been phased out.) Upstream signals from cable modems and two-way set-top boxes are generally carried on specific frequencies chosen by the cable company. **Table 27.2** summarizes cable downstream channel allocations that overlap Amateur Radio bands. The complete North American channel plan is controlled by EIA standard 542-B. A summary of the channel structure for North America is maintained at **en.wikipedia.org/wiki/North_American_television_frequencies#cite_note-14.**

## COMMON MECHANISMS FOR LEAKAGE AND INGRESS

As noted previously, cable TV leakage and ingress occur when the shielding integrity of the cable network is compromised. A large cable system that serves a major metropolitan area has literally millions of connectors, tens of thousands of miles of coaxial cable, thousands of amplifiers, hundreds of thousands of passives (splitters, directional couplers, and similar devices), and uncountable customer premises equipment connected to the cable network! Any of these may be a source of leakage and ingress.

## DIGITAL SIGNAL LEAKAGE

The digitally modulated signals carried in a cable TV network use 64-QAM or 256-QAM, the latter more common. (See the **Modulation** chapter for more information on Digital TV modulation.) If a QAM signal were to leak from a cable TV network, it is possible for interference to an over-the-air service to occur, but very unlikely to be identified as from a digital TV signal. The reason for this is that a QAM signal is noise-like, and sounds like normal background noise or hiss on a typical amateur receiver. The QAM signal's digital channel power — its average power over the entire occupied bandwidth — is typically 6 to 10 dB lower than what an analog TV signal's visual carrier peak envelope power (PEP) would be on the same channel. As well, a QAM signal occupies most of the 6 MHz channel slot, and there are no carriers *per se* within that channel bandwidth. Note that over-the-air 8-VSB digital TV broadcast signals transmit a pilot carrier near the lower end of the digital "haystack," but the QAM format used by cable operators has no comparable pilot carrier.

What makes the likelihood of interference occurring (or not occurring) has in large part to do with the behavior of a receiver in the presence of broadband noise. While each downstream cable TV QAM signal occupies close to 6 MHz of RF bandwidth, the IF bandwidth of a typical amateur FM receiver might be approximately 20 kHz. Thus, the noise power in the receiver will be reduced by 10 $\log_{10}$ (6,000,000/20,000) = 24.77 dB because of the receiver's much narrower IF bandwidth compared to the QAM signal's occupied bandwidth. In addition, there is the 6 to 10 dB reduction of the digital signal's average signal PEP.

Field tests during 2009 confirmed this behavior, finding that a leaking QAM signal would not budge the S meter of a Yaesu FT-736R at low to moderate field strength leaks, even when the receiver's antenna — a resonant half-wave dipole — was located just 10 feet from a calibrated leak. In contrast, a CW carrier that produced a 20 μV/m leak resulted in an S meter reading of S9 +15 dB, definitely harmful interference! When the CW carrier was replaced by a QAM signal whose digital channel power was equal to the CW carrier's PEP and which produced the same leakage field strength (the latter integrated over the full 6 MHz channel bandwidth), the S-meter read <S1. When the leakage field strength was increased to 100 μV/m, the CW carrier pegged the S meter at S9 +60 dB, while the QAM signal was S3 in FM mode and between S1 and S2 in USB mode. It wasn't until the leaking QAM signal's field strength reached

**Table 27.2**
**Amateur Radio Bands Relative to Cable TV Downstream Channels**

| 22 | 169.25 | 168.0084 | 169.25 | 173.75 |

several hundred µV/m that the "noise" (and it literally sounded like typical white noise) could be construed to be harmful interference.

One of the most common signs of possible leakage is interference to the 2 meter amateur band, especially in the vicinity of standard (STD) cable channel 18's visual carrier on 145.25 MHz. If you suspect cable leakage, listen for the telltale broadband noise from the digital video signal over the 144-150 MHz range, and check other STD, incrementally related carrier (IRC), and harmonically related carrier (HRC) visual carrier frequencies on nearby channels listed in **Table 27.3** using a wide range receiver or scanner. (Leakage of an analog TV signal on cable channel 18 sounds like buzzing at the carrier frequencies in the table on or near 145.25 MHz. Also listen for TV channel sound on the FM aural carriers 4.5 MHz above the visual carriers.)

### LOCATING LEAKAGE SOURCES

When a cable company technician troubleshoots signal leakage, the process is similar to Amateur Radio fox hunting. The technician uses radio direction finding techniques that may include equipment such as handheld dipole or Yagi antennas, Doppler antenna arrays on vehicles, near-field probes, and commercially manufactured signal leakage detectors. Many leakage detectors incorporate what is known as "tagging" technology to differentiate a leaking cable signal from an over-the-air signal or electrical noise that may exist on or near the same frequency. Most leakage detection is done on a dedicated cable channel in the 108-138 MHz frequency range.

### ELIMINATING LEAKAGE

A large percentage of leakage and ingress problems are not the result of a single shielding defect, although this does happen. For example, a squirrel might chew a hardline feeder cable, or a radial crack might develop in the shield as a consequence of environmental or mechanical damage. Most often, leakage and ingress are caused by several small shielding defects in an area: loose or corroded hardline connectors and splices, old copper braid subscriber drop cabling, improperly installed F connectors, subscriber-installed substandard "do-it-yourself" components, and the previously mentioned poorly shielded cable-ready TVs and other *customer premises equipment* (*CPE*).

Other leakage and ingress problems can be caused by improper shield connections at the cable TV set-top box. The return data signal in the low HF region (3.7-5.5 MHz) can be radiated in this way, as well. Common-mode chokes at the equipment with the poor shield connection can block the RF current.

After the cable technician locates the source(s) of the leakage, it is necessary to repair or replace the culprit components or cabling. In the case of poorly shielded TVs or DVD players, the cable technician cannot repair those devices, only recommend that they be fixed by a qualified service shop. Often the installation of a set-top box will take care of a cable-ready CPE problem because the subscriber drop cabling is no longer connected directly to the offending device.

It is important to note that interference from leakage that is received over the air cannot be eliminated at the receiver. It is an "in-band" signal just like the desired signal and can't be filtered out or suppressed with chokes. It must be eliminated at the source of the leakage.

Similarly, RFI from cable ingress — where a clean, transmitted signal gets into the cable system signals through similar defects to those that cause leakage — must also be eliminated at the point at which the transmitted signal enters the cable system.

In both cases, a little RFI detective work may be necessary. Refer to the various RFI troubleshooting sections of this chapter and radio direction finding techniques may come in handy, as well. Once the source of leakage or point of ingress is determined, like power-line noise, it becomes the job of the cable company to repair.

### VERIFYING AN RFI SOURCE TO BE LEAKAGE

Spurious signals, birdies, harmonics, intermodulation, electrical noise, and even interference from Part 15 devices are sometimes mistaken for cable signal leakage. One of the most common is emissions from Part 15 devices that become coupled to the cable TV coax shield in some way. Non-leakage noise or spurious signals may radiate from the cable TV lines or an amplifier location, but only because the outer surface of the cable shield is carrying the coupled interference as a common-mode current.

A common non-leakage interference that may radiate from a cable network is broadband electrical interference or other noise in the MF and lower end of the HF spectrum. A common misconception is that since cable companies carry digital signals on frequencies that overlap portions of the over-the-air spectrum below 30 MHz, any "noise" that radiates from the cable plant must be leaking digital signals. This type of interference is almost always power-line electrical interference or other noise that is coupled to the cable network's shield as a common-mode signal.

Leakage of downstream digital signals sound like broadband noise as described above, over a range of frequencies given in the channels of Table 27.3. Upstream digital signals from cable modems, which have channel bandwidths of 1.6, 3.2 or 6.4 MHz, are typically transmitted in the roughly 20 to 40 MHz range, and are bursty in nature rather than continuous like downstream digital signals. Set-top box upstream telemetry carriers are narrowband frequency shift keying (FSK) or quadrature phase shift keying (QPSK) carriers usually in the approximately 8 to 11 MHz range.

If normal leakage troubleshooting techniques do not clearly identify the source of the interference, sometimes the cable company may temporarily shut off its network in the affected neighborhood. If the interference remains after the cable network is turned off, it is not leakage, and the cable company is not responsible for that type of interference. If the interference disappears when the cable network is turned off, then it most likely is leakage or something related to the cable network. Turning off even a small portion of the cable network is a last resort and may not be practical because of the service disruption to subscribers. It may be easier for the cable company to temporarily shut off a suspect cable channel briefly. Here, too, if the interference remains after the channel is turned off, the interference is not leakage.

### HOW TO REPORT LEAKAGE

If you suspect cable signal leakage is causing interference to your amateur station, *never attempt your own repairs to any part of the cable network, even the cabling in your own home*! Document what you have observed. For instance, note the frequency or frequencies involved, the nature of the interference, any changes to the interference with time of day, how long it has been occurring, and so forth. If you have fox-hunting skills and equipment, you might note the probable source(s) of the interference or at least the direction from which it appears to be originating.

Next, contact the cable company. You will most likely reach the cable company's customer service department, but ask to speak with the local cable system's Plant Manager (may also be called Chief Engineer, Director of Engineering, Chief Tech, VP of Engineering, or similar), and explain to him or her that you are experiencing what you believe to be signal leakage-related interference. If you cannot reach this individual, ask that a service ticket be created, and a technician familiar with leakage and ingress issues be dispatched. Share the information you have gathered about the interference. And as with all RFI issues, remember diplomacy!

In the vast majority of cases when cable leakage interference to Amateur Radio occurs, it is able to be taken care of by working with local cable system personnel. Every now and then for whatever reason, the affected ham is unable to get the interference resolved locally. Contact the ARRL for help in these cases.

### 27.8.5 DVD and Video Players

A DVD or similar video player usually contains a television tuner. Older models may have an analog TV channel output. (Newer models typically have an HDMI digital video interface which is less susceptible to RFI.) It is also connected to an antenna or cable system and the ac line, so it is subject to all of the interference problems of a TV receiver. Start by proving that the video player is the susceptible device. Temporarily disconnect the device from the television or video monitor. If there is no interference to the TV, then the video player is the most likely culprit. (Cables between the video player and monitor can also be the means by which RF is getting into the monitor, so a cable dummy (see the sidebar) may be a useful way to determine if that is the case and which cable or cable(s) are the problem.)

Next, find out how the interfering signal is getting into the video player. Temporarily disconnect the antenna or cable feed line from the video player. If the interference goes away, then the antenna line is involved. In this case, you can probably fix the problem with a common-mode choke or high-pass filter.

Figure 27.21 shows a bulletproof video player installation. If you have tried all of the cures shown and still have a problem, the player is probably subject to direct pickup. In this case, you can replace it or contact the manufacturer through the CEA.

Older analog-type VCRs are quite susceptible to RFI from HF signals. The video baseband signal extends from 30 Hz to 3.5 MHz, with color information centered around 3.5 MHz and the FM sound subcarrier at 4.5 MHz. The entire video baseband is frequency modulated onto the tape at frequencies up to 10 MHz. Direct pickup of strong signals by VCRs is a common problem and may not be easily solved, short of replacing the VCR with a better-shielded model or a modern DVD player.

### 27.8.6 Non-Radio Devices

Interference to non-radio devices is not the fault of the transmitter. (A portion of the *FCC Interference Handbook*, 1990 Edition, is shown in **Figure 27.22**. Although the FCC no longer offers this *Handbook*, an electronic version is available in this book's downloadable supplemental information, from the ARRL at **www.arrl.org/fcc-rfi-information** or search the ARRL website for "cib interference handbook".) In essence, the FCC views non-radio devices that pick up nearby radio signals as improperly functioning; contact the manufacturer and return the equipment. The FCC does not require that non-radio devices include RFI protection and they don't offer legal protection to users of these devices that are susceptible to interference.

#### TELEPHONES

Landline or "wired" telephones present a very common non-TVI interference problem to Amateur Radio. As more people switch over to mobile telephone service instead of landline, this problem is gradually diminishing. Nevertheless, landline and cordless phones which are connected to the landline will continue to be with us for many years. Most cases of telephone interference to these phones can be cured by correcting any installation defects and installing telephone RFI filters where needed. The remainder of this section assumes the telephone is connected to landline service.

Telephones can improperly function as radio receivers. Semiconductor devices inside many telephones act like diodes. When such a telephone is connected to the telephone wiring (a large antenna) an AM radio receiver can be formed. When a nearby transmitter goes on the air, these telephones can be affected.

Troubleshooting techniques were discussed earlier in the chapter. The suggestion to simplify the problem applies especially to telephone interference. Disconnect all telephones except one, right at the service entrance if possible, and start troubleshooting the problem there.

If any single device or bad connection in the phone system detects RF and puts the detected signal back onto the phone line as audio, that audio cannot be removed with filters. Once the RF has been detected and turned into audio, it cannot be filtered out because the interference is at the same frequency as the desired audio signal. To effect a cure, you must locate the detection point and correct the problem there.

Defective telephone company lightning arrestors can act like diodes, rectifying any nearby RF energy. Telephone-line amplifiers or other electronic equipment may also be at fault. Do not attempt to diagnose or repair any telephone company wiring or devices on the "telco" side of your service box or that were installed by the phone company. Request a service call from your phone company.

Inspect the telephone system installation. Years of exposure in damp basements, walls or crawl spaces may have caused deterioration. Be suspicious of anything that is corroded or discolored. In many cases, homeowners have installed their own telephone wiring, often using substandard wiring. If you find sections of telephone wiring made from nonstandard cable, replace it with standard twisted-pair telephone or CAT5 cable. If you

# PART II

# INTERFERENCE TO OTHER EQUIPMENT

## CHAPTER 6

## TELEPHONES, ELECTRONIC ORGANS, AM/FM RADIOS, STEREO AND HI-FI EQUIPMENT

Telephones, stereos, computers, electronic organs and home intercom devices can receive interference from nearby radio transmitters. When this happens, the device improperly functions as a radio receiver. Proper shielding or filtering can eliminate such interference. The device receiving interference should be modified in your home while it is being affected by interference. This will enable the service technician to determine where the interfering signal is entering your device.

The device's response will vary according to the interference source. If, for example, your equipment is picking up the signal of a nearby two-way radio transmitter, you likely will hear the radio operator's voice. Electrical interference can cause sizzling, popping or humming sounds.

**Figure 27.22 — Part of page 18 from the FCC *Interference Handbook* (1990 edition) explains the facts and places responsibility for interference to non-radio equipment.**

do use telephone cable, be sure it is high-quality twisted-pair to minimize differential-mode pickup of RF signals.

Next, evaluate each of the telephone instruments. If you find a susceptible telephone, install a telephone RFI filter on that telephone, such as those sold by K-Y Filters. (**www.ky-filters.com**) or use DSL filters that keep the DSL data signals out of the telephones. If the home uses a DSL broadband data service, be sure that the filters do not affect DSL performance by testing online data rates with and without a filter installed at the telephone instrument.

If you determine that you have interference only when you operate on one particular ham band, the telephone wiring system either has an "RF hot spot" at that point when excited on that band or some cable in the system could be resonant and thus especially responsive on that band. Install common-mode chokes on the wiring to add a high impedance in series with the "antenna." A telephone RFI filter may also be needed. (See the section on DSL Equipment for filtering suggestions.)

***Telephone Accessories*** — Answering machines and fax machines (two more telephone-related instruments that are slowly disappearing) are also prone to interference problems. All of the troubleshooting techniques and cures that apply to telephones also apply to these telephone devices. In addition, many of these devices connect to the ac mains. Try a common-mode choke and/or ac-line filter on the power cord (which may be an ac cord set, a small transformer or power supply).

***Cordless Telephones*** — A cordless telephone is an unlicensed *radio* device that is manufactured and used under Part 15 of the FCC regulations. The FCC does not intend Part 15 devices to be protected from interference. These devices usually have receivers with very wide front-end filters, which make them very susceptible to interference.

A likely path for interference to cordless phones is as common-mode current on the base unit's connecting cables that will respond to common-mode chokes. In addition, a telephone filter on the base unit and an ac line filter may help. The best source of help is the manufacturer but they may point out that the Part 15 device is not protected from interference.

Newer cordless phone systems operating at 900 MHz and higher frequencies are often less susceptible to interference than older models are less susceptible to interference.

## AUDIO EQUIPMENT

Consumer and commercial audio equipment such as stereos, home entertainment systems, intercoms and public-address systems can also pick up and detect strong nearby transmitters. The FCC considers these non-radio devices and does not protect them from licensed radio transmitters that may interfere with their operation. The RFI can be caused by one of several things: pickup on speaker leads or interconnecting cables, pickup by the ac mains wiring or direct pickup. If the interference involves wiring connected to the affected device, common-mode chokes are the most likely solution.

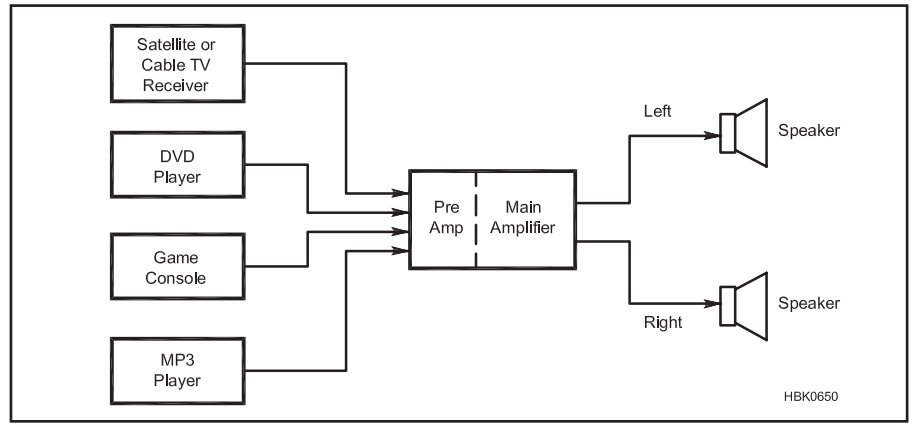

**Figure 27.23 — A typical modern home-entertainment system.**

Use the standard troubleshooting techniques discussed earlier in this chapter to isolate problems. In a multi-component home entertainment system (as in **Figure 27.23**), for example, you must determine what combination of components is involved with the problem. First, disconnect all auxiliary components to determine if there is a problem with the main receiver/amplifier. Long speaker or interconnect cables are prime suspects.

***Stereos and Home Entertainment Systems*** — If the problem remains with the main amplifier isolated, determine if the interference level is affected by the volume control. If so, the interference is getting into the circuit *before* the volume control, usually through accessory wiring. If the volume control has no effect on the level of the interfering sound, the interference is getting in *after* the control, usually through speaker wires.

*Speaker wires* are often effective antennas on HF and sometimes into VHF and above. The speaker terminals are often connected directly to the output amplifier transistors. Modern amplifier designs use a negative feedback loop to improve fidelity. This loop can conduct the detected RF signal back to the high-gain stages of the amplifier. The combination of all of these factors often makes the speaker cables the dominant receiving antenna for RFI.

There is a simple test that will help determine if the interfering signal is being coupled into the amplifier by the speaker leads. Temporarily disconnect the speaker leads from the amplifier, and plug in a test set of headphones with short leads. If there is no interference with the headphones, filtering the speaker leads will likely cure the problem.

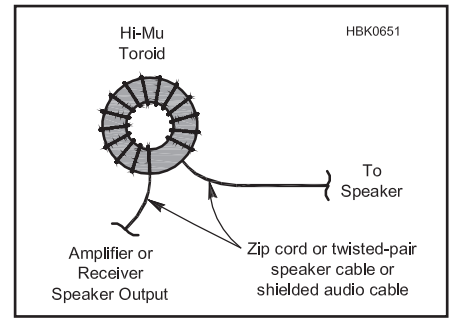

**Figure 27.24 — Making a speaker-lead common-mode choke. Use ferrite material appropriate for the frequency of the RF interference.**

Start by applying common-mode chokes. **Figure 27.24** shows how to wrap speaker wires around an large (2-inch O.D. or larger) ferrite core to cure speaker-lead RFI. Type 31 material is preferred at HF. (See the section on Common-Mode Chokes in this chapter.)

In some cases, the speaker wires may be picking up RF as a differential-mode signal. To reduce differential-mode pickup, replace the zip cord speaker wire with twisted-pair wire. (#16 AWG will work for most systems with higher-power systems requiring #12 AWG.)

***Powered Speakers*** — A powered speaker is one that has its own built-in power amplifier. Powered subwoofers are common in home entertainment systems and small powered speakers are often used with computer and gaming systems. If a speaker runs on batteries and/or an external power supply, or is plugged into mains power, it is a powered loudspeaker. Powered loudspeakers are notoriously susceptibility to common-mode interference from internally misconnected cable shields and poor shielding. Apply suitable common-mode chokes to all wiring, including power wiring. If the RFI persists, try an RF filter

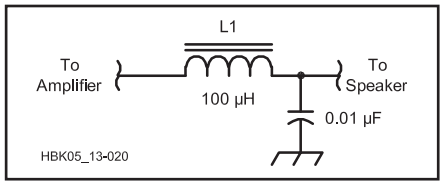

**Figure 27.25 — A low-pass LC filter.**

at the input to the speaker, such as the LC low-pass filter in **Figure 27.25**. Unshielded speakers may not be curable, however.

***Intercoms and Security Systems*** — RFI to these systems is nearly always caused by common-mode current on interconnect wiring. Common-mode chokes are the most likely cure, but you may also need to contact the manufacturer to see if they have any additional, specific information. Twisted-pair wiring (CAT5 network cable contains four such pairs) should be used, including for audio output wiring. Wiring can often be complex, so any work on these systems should be done by a qualified sound contractor.

***Public-Address Systems*** — Common-mode current is also the culprit here. Powered speakers are increasingly used and can be treated as described above. Work to remove interference should be done by the installing contractor and may require coordination between the amateur and contractor to characterize the interference and provide test assistance while the work is being done.

## COMPUTERS AND OTHER UNLICENSED RF SOURCES

Computers and microprocessor-based devices such as video games or audio players can be sources or victims of interference. These devices contain oscillators that can and do radiate RF energy. In addition, the internal functions of a computer generate different frequencies, based on the various data signals. All of these signals are digital — with fast rise and fall times that are rich in harmonics.

Computing devices are covered under Part 15 of the FCC regulations as unintentional emitters. As for any other unintentional emitter, the FCC has set absolute radiation limits for these devices. As previously discussed in this chapter, FCC regulations state that the operator or owner of Part 15 devices must take whatever steps are necessary to reduce or eliminate any interference they cause to a licensed radio service. This means that if your neighbor's video game interferes with your radio, the neighbor is responsible for correcting the problem. (Of course, your neighbor may appreciate your help in locating a solution!)

The FCC has set up two tiers of limits for computing devices. Class A is for computers used in a commercial environment. FCC Class B requirements are more stringent — for computers used in residential environ-

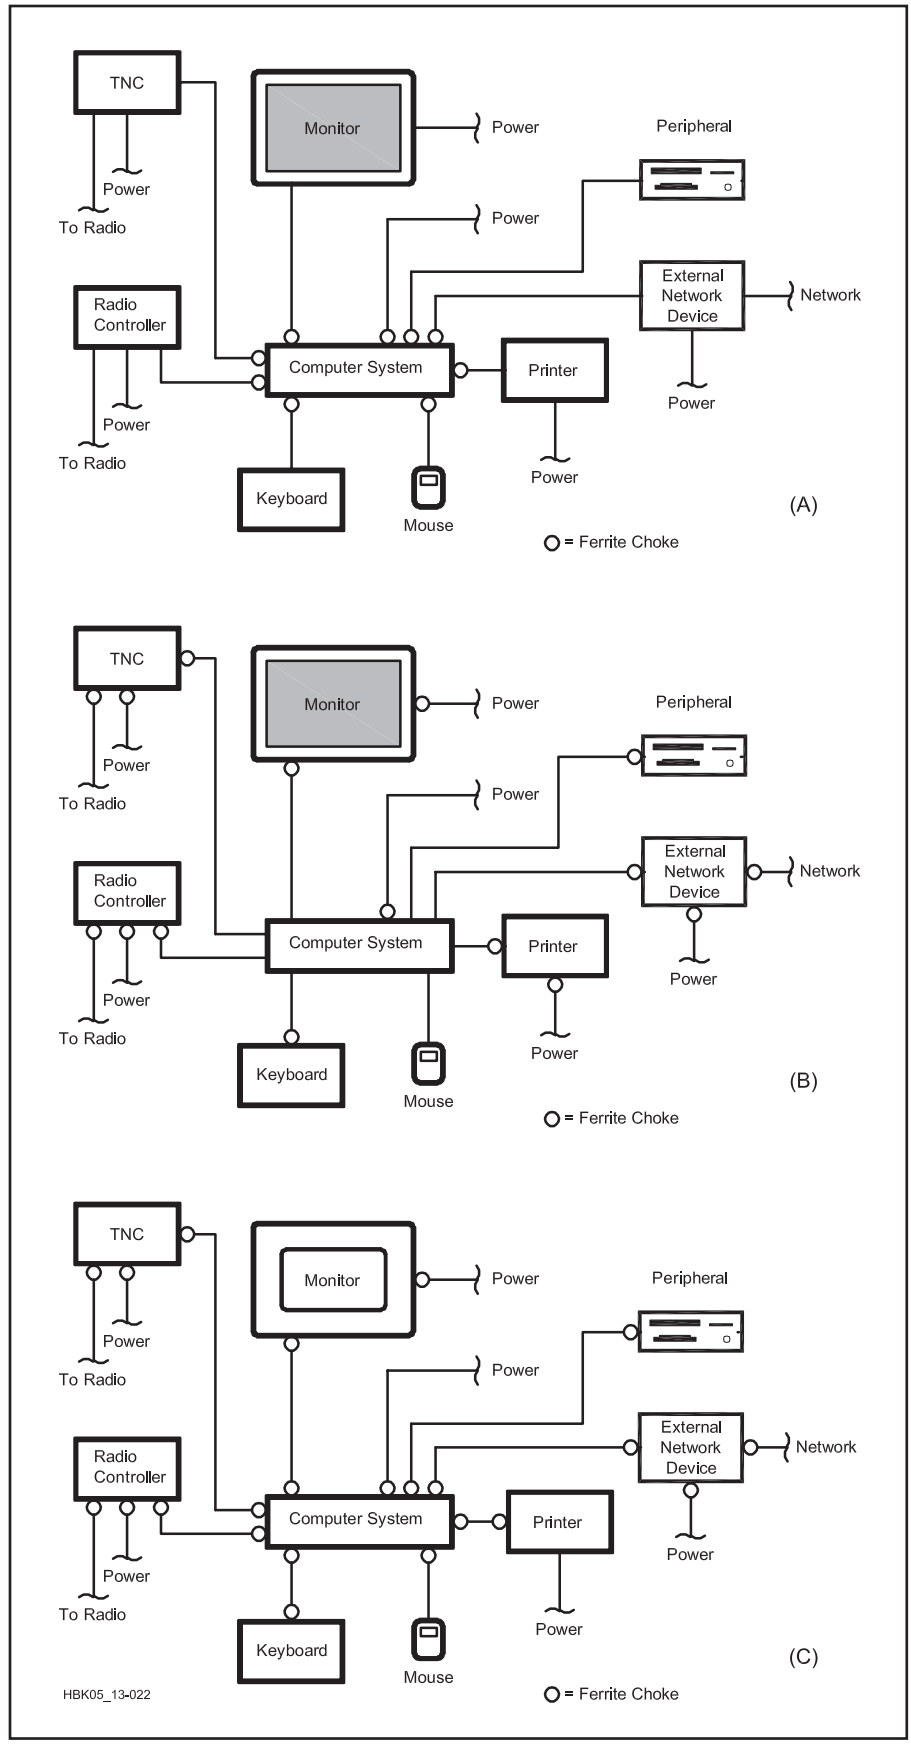

**Figure 27.26 — Where to locate ferrite chokes in a computer system. At A, the computer is noisy, but the peripherals are quiet. At B, the computer is quiet, but external devices are noisy. At C, both the computer and externals are noisy.**

ments. If you buy a computer or peripheral, be sure that it is Class B certified or it will probably generate interference to your amateur station or home-electronics equipment.

If you find that your computer system is interfering with your radio (not uncommon in this digital-radio age), start by simplifying the problem. Temporarily remove power from as many peripheral devices as possible and disconnect their cables from the back of the computer. (It is necessary to physically remove the power cable from the device, since many devices remain in a low-power state when turned off from the front panel or by a software command.) If possible, use just the computer, keyboard and monitor. This test may identify specific peripherals as the source of the interference.

It can be difficult to determine whether peripheral connecting cables are shielded. If possible, use shielded cables for all peripherals. Replace any unshielded cables with shielded ones; this often significantly reduces RF noise from computer systems. The second line of defense is the common-mode choke. The choke should be installed as close to the computer and/or peripheral device as practical. **Figure 27.26** shows the location of common-mode chokes in a complete computer system where both the computer and peripherals are noisy. USB-power devices can also create noise from internal power supplies and are discussed in K9YC's *National Contest Journal* paper, "Killing Receive Noise – Part 1 and 2," included in the downloadable supplemental information for this chapter.

A multi-turn common-mode choke wound for the HF bands is often ineffective at VHF. When VHF antennas are located close to these devices (or if a more distant beam is pointed at them), it may also be necessary to add one or two 2-turn chokes to suppress noise on 6 meters and multiple, single-turn, clamp-on cores for 2 meter noise. The cores for the higher frequencies should always be placed closest to the noise source, and when two pieces of digital equipment are connected, each should be considered a potential source, so VHF cores may be needed on both ends.

Switchmode power supplies in computers are often sources of interference. A common-mode choke and/or ac-line filter may cure this problem. In extreme cases of computer interference you may need to improve the shielding of the computer. (Refer to the *ARRL RFI Book* for more information about this.) Don't forget that some peripherals (such as modems) are connected to the phone line, so you may need to treat them like telephones.

## GROUND-FAULT AND ARC-FAULT CIRCUIT INTERRUPTORS (GFCI AND AFCI)

GFCIs are occasionally reported to "trip" (open the circuit) when a strong RF signal, such as an amateur's HF transmission, is present. GFCI circuit breakers operate by sensing unbalanced currents in the hot and neutral conductors of an ac circuit. In the absence of RF interference, such an imbalance indicates the presence of a fault somewhere in the circuit, creating a shock hazard. The breaker then trips (opens) to remove the shock hazard.

An Arc Fault Circuit Interrupter (AFCI) circuit breaker is similar in that it monitors current to watch for a fault condition. Instead of current imbalances, the AFCI detects patterns of current that indicate an arc — one of the leading causes of home fires. The AFCI is not supposed to trip because of "normal" arcs that occur when a switch is opened or a plug is removed.

Under current codes, GFCI protection is required for all basement outlets, outdoor outlets, and for outlets in kitchens and bathrooms. AFCI protection is now required for all circuits that supply bedrooms and other areas of a home as well. Code requirements can vary so be sure to check with your local building inspector for those that apply in a specific case.

RF interference to GFCI breakers is caused by RF current or voltage upsetting normal operation of the imbalance detection circuit, resulting in the false detection of a fault. Similarly, RF current or voltage could upset the arc detection circuitry of an AFCI breaker. Some early GFCI breakers were susceptible to RFI, but as the technology has improved, fewer and fewer such reports have been received. While it is possible to add filtering or RF suppression to the breaker wiring, a simpler and less expensive solution is to replace the GFCI breaker with a new unit less susceptible to RF.

The ARRL Lab has received favorable reports on the following GFCI products:

- Leviton (**www.leviton.com**) GFCI outlets which are available in both 15 and 20 A versions for 120 V ac circuits as well as cord sets and user-attachable plugs and receptacles.
- Bryant (**www.bryant-electric.com**) ground fault receptacles which feature published 0.5 V immunity from 150 kHz to 230 MHz.
- Cooper (**www.cooperindustries.com**) GFCI products that are labeled "UL 943 compliant" on the package.

A web page on the ARRL website is maintained on GFCI/AFCI technology (**www.arrl.org/gfci-and-afci-devices**). Reports have not been received on AFCI products as of early 2013. Although there have been numerous reported immunity problems with AFCI products, they are now greatly reduced. Manufacturers seem to have largely fixed these issues. See **www.arrl.org/afci-devices** for more information.

## WALL TRANSFORMER SWITCHING SUPPLIES

While small, low-current linear power supplies known as "wall warts" have been widely used for many years, it is now becoming common for these devices to contain switchmode or "switcher" supplies. Because they must be manufactured very inexpensively, these supplies often have little or no RF filtering at either the ac input or dc output, frequently creating significant RFI to nearby amateurs.

The least expensive course of action may be to simply replace the switchmode supply with a linear model. If the system in which the supply is used is still under warranty, the distributor or manufacturer may be able to replace it. Otherwise, a third-party linear replacement may be available with the same voltage rating and current output equal to or higher than the original supply. Adapters may be available to convert output connector styles where necessary or new connectors installed. Older linear-style supplies can be re-used if you are willing to splice them in to replace the switchmode model.

If replacing the supply with a linear model is not an option, you will have to apply RF filters to the supply. These supplies are rarely serviceable, so filters much be installed externally. Noise is usually radiated from the output cable so winding the cable onto a ferrite core creates a common-mode RF choke as described in this chapter's Elements of RFI Control section. Since the wall-wart style supply plugs directly into a wall-mounted receptacle, a short ac extension cord or power strip cord can be made into a common-mode choke, as well.

# 27.9 Automotive RFI

Automobiles have evolved from a limited number of primitive electrical components to high technology, multi-computer systems on-wheels. Every new technology deployed can potentially interfere with amateur equipment.

Successful mobile operation depends on a multitude of factors such as choosing the right vehicle, following installation guidelines, troubleshooting and deploying the appropriate RFI fixes as needed.

A number of these factors will be covered in this section. Additionally, newly emerging electrical and hybrid-electric vehicles will be discussed, which pose unique challenges to amateur equipment installations and operation.

## 27.9.1 Before Purchasing a Vehicle

When shopping for a new vehicle intended for a mobile amateur installation, begin with research. A wealth of information is available on the Internet, and specifically at **www.arrl.org/automotive**, where the ARRL has compiled years of data from automotive manufacturers and other hams. Email reflectors and websites may provide information from hams willing to share their experiences concerning mobile communications in their own vehicles that may be the very make and model you were considering.

Armed with research, your next stop is your dealer. The manufacturer of each vehicle is the expert on how that vehicle will perform. The dealer should have good communication with the manufacturer and should be able to answer your questions. Ask about service bulletins and installation guidelines. You can also ask your dealer about fleet models of their vehicles. Some manufacturers offer special modifications for vehicles intended for sale to police, taxicabs and other users who will be installing radios (usually operating at VHF and UHF) in their cars.

When shopping for a vehicle, it is useful to take along some portable (preferably battery operated) receivers or scanners and have a friend tune through your intended operating frequencies while you drive the vehicle. This will help identify any radiated noise issues associated with that model vehicle, which can be more difficult to resolve than conducted noise. If you intend to make a permanent transceiver installation, give some consideration to how you will mount the transceiver and route the power and/or antenna cables. While looking for ways to route the wiring, keep in mind that some newer cars have the battery located in the trunk or under the rear seat, and that may make power wire routing easier.

Test the car before you buy it. A dealer expects you to take the car for a test ride; a cooperative dealer may let you test it for radio operation, too. A fair amount of checking can easily be performed without digging too deeply into the car. Check the vehicle for noise with a portable receiver on VHF, where your handheld transceiver will do the job nicely. On HF, you can usually locate noise with a portable short-wave receiver, or operate your HF transceiver with a portable antenna and cigarette-lighter plug. With the engine running, tune across the bands of interest. You may hear some noise, or a few birdies, but if the birdies don't fall on your favorite frequency, this is an encouraging sign! Check with the vehicle completely off, with the key in the ignition, and with the vehicle running — electronic subsystems operate in different ways with the vehicle running or not running.

To test the vehicle for susceptibility to your transmitted signal, you must transmit. It is important to note that without a full and complete installation, you will not be able to fully assess the effects of full-power transmissions on a vehicle. Any testing done with temporary equipment installations cannot be considered an absolute guarantee because an installed transmitter connected directly to the vehicle's power source may cause the vehicle to act differently.

To perform transmit tests, bring your radio and a separate battery (if permitted by dealer) so you can transmit at full power while in motion without having to run cables to the vehicle battery. Use a magnet-mount antenna (several *QST* advertisers sell mounts suitable for HF) for temporary testing. (Use the magnet-mount carefully; it is possible to scratch paint if any particles of dirt get on the bottom of the magnets.) Transmit on each band you will use to see if the RF has any effect on the vehicle. Lack of response to your transmissions is a good sign, but does not mean the vehicle is immune to RF as a permanent installation will result in different (likely stronger) field strengths and distributions in and around the vehicle and a permanent antenna more effectively coupled to the vehicle.

On both transmit and receive, you may want to experiment with the placement of the antenna. Antenna placement plays an important role in operation, and you may be able to find an optimal location for the antenna that predicts good performance with a permanent installation.

## 27.9.2 Transceiver Installation Guidelines

While most amateurs are familiar with the process of installing a transceiver, there are preferred practices that will help minimize potential problems. These include support from the automotive dealer, typical "best practices" installations, and consideration of special situations.

The first step is to ensure that your installation complies with both the vehicle manufacturer's and radio transceiver manufacturer's installation guidelines. Links to domestic automotive manufacturer installation guidelines are found at **www.arrl.org/automotive**. Automotive manufacturers that import vehicles for sale here do not publish installation guidelines because their vehicles are not typically used in police, fire and taxicab applications within the US.

The installation guidelines of different manufacturers vary as to how to install a radio transceiver's power leads. Most manufacturers recommend that the positive and negative leads from the radio be run directly to the battery. This minimizes the potential for the interaction between the radio's negative lead currents and vehicle electronics. If the manufacturer recommends that both wires be connected to the battery, they will also require that both wires be fused. This is necessary because, in the unlikely event that the connection between the battery and the engine block were to fail, excessive current could be drawn on the radio's negative lead when the vehicle starter is engaged.

Some vehicles provide a "ground block" near the battery for a negative cable to be connected. On these vehicles, run the negative power lead, un-fused, to the "ground block." When this technique is recommended by the manufacturer, the interaction between the power return currents and vehicle electronics has been evaluated by the manufacturer. In all cases, the most important rule to remember is this: If you want the manufacturer to support your installation, do it exactly the way the installation guidelines tell you to do it!

If no installation guidelines are available for your vehicle, the practices outlined below will improve compatibility between in-vehicle transceivers and vehicle electronics:

1) Transceivers

- Transceivers should be mounted in a location that does not interfere with vehicle operator controls and visibility, provides transceiver ventilation, and be securely mounted.
- Ensure all equipment and accessories are removed from the deployment path of the airbag and safety harness systems.

2) Power Leads

- The power leads should be twisted together from the back of the rig all the way to the battery. This minimizes the area formed by the power leads, reducing susceptibility to transients and RFI.
- Do not use the vehicle chassis as a power return.

• The power leads should be routed along the body structure, away from vehicle wiring harnesses and electronics.

• Any wires connected to the battery should be fused at the battery using fuses appropriate for the required current.

• Use pass-through grommets when routing wiring between passenger and engine compartments.

• Route and secure all under hood wiring away from mechanical hazards.

3) Coaxial Feed Lines

• The coaxial feed line should have at least 95% braid coverage. The cable shield should be connected to every coaxial connector for the entire circumference (no "pigtails").

• Keep antenna feed lines as short as practical and avoid routing the cables parallel to vehicle wiring.

4) Antennas

• Antenna(s) should be mounted as far from the engine and the vehicle electronics as practical. Typical locations would be the rear deck lid or roof. Metal tape can be used to provide an antenna ground plane on nonmetallic body panels.

• Care should be used in mounting antennas with magnetic bases, since magnets may affect the accuracy or operation of the compass in vehicles, if equipped.

• Since the small magnet surface results in low coupling to the vehicle at HF, it is likely that the feed line shield will carry substantial RF currents. A large (2-inch OD or larger toroid) common-mode choke at the antenna will help reduce this current, but will also reduce any radiation produced by that current.

• Adjust the antenna for a low SWR.

## 27.9.3 Diagnosing Automotive RFI

Most VHF/UHF radio installations should result in no problems to either the vehicle systems or the transceiver, while HF installations are more likely to experience problems. In those situations where issues do occur, the vast majority are interference to the receiver from vehicle on-board sources of energy that are creating emissions within the frequency bands used by the receiver. Interference to one of the on-board electronic systems can be trivial or it can cause major problems with an engine control system.

The dealer should be the first point of contact when a problem surfaces, because the dealer should have access to information and factory help that may solve your problem. The manufacturer may have already found a fix for your problem and may be able to save your mechanic a lot of time (saving you money in the process). If the process works properly, the dealer/customer-service network can be helpful. In the event the dealer is unable to solve your problem, the next section includes general troubleshooting techniques you can perform independently.

### GENERAL TROUBLESHOOTING TECHNIQUES

An important aspect is to use the source-path-victim model presented earlier in this chapter. The path from the source to the receiver may be via radiation or conduction. If the path is radiation, the electric field strength (in V/m) received is reduced as a function of the distance from the source to the receiver. In most cases, susceptible vehicle electronics is in the near-field region of the radiating source, where the electric and magnetic fields can behave in complex ways. In general, however, the strength of radiated signals falls off with distance.

The best part of all this is that with a general-coverage receiver or spectrum analyzer, a fuse puller and a shop manual, the vehicle component needing attention may be identified using a few basic techniques. The only equipment needed could be as simple as:

• A mobile rig, scanner or handheld transceiver, or

• Any other receiver with good stability and an accurate readout, and

• An oscilloscope for viewing interference waveforms

### BROADBAND NOISE

Automotive broadband noise sources include:

• Electric motors such as those that operate fans, windows, sunroof, AM/FM antenna deployment, fuel pumps, etc.

• Ignition spark

If you suspect electric motor noise is the cause of the problem, obtain a portable AM or SSB receiver to check for this condition. Switch on the receiver and then activate the electric motors one at a time. When a noisy motor is switched on, the background noise increases. It may be necessary to rotate the radio, since portable AM radios use a directional ferrite rod antenna.

To check whether fuel pumps, cooling fans, and other vehicle-controlled motors are the source of noise, pull the appropriate fuse and see whether the noise disappears.

A note concerning fuel pumps: virtually every vehicle made since the 1980s has an electric fuel pump, powered by long wires. It may be located inside the fuel tank. Don't overlook this motor as a source of interference just because it may not be visible. Electric fuel-pump noise often exhibits a characteristic time pattern. When the vehicle ignition switch is first turned on, without engaging the starter, the fuel pump will run for a few seconds, and then shut off when the fuel system is pressurized. At idle, the noise will generally follow the pattern of being present for a few seconds before stopping, although in some vehicles the fuel pump will run almost continuously if the engine is running.

### NARROWBAND NOISE

Automotive narrowband noise sources include:

• Microprocessor based engine control systems

• Instrument panel

• RADAR obstacle detection

• Remote keyless entry

• Key fob recognition systems

• Tire pressure monitoring systems

• Global positioning systems

• Pulse width modulating motor speed controls

• Fuel injectors

• Specialized electric traction systems found in newer hybrid/electric vehicles

Start by moving the antenna to different locations. Antenna placement is often key to resolving narrowband RFI problems. However, if antenna location is not the solution, consider pulling fuses. Tune in and stabilize the noise, then find the vehicle fuse panels and pull one fuse at a time until the noise disappears. If more than one module is fed by one fuse, locate each module and unplug it separately. Some modules may have a "keep-alive" memory that is not disabled by pulling the fuse. These modules may need to be unplugged to determine whether they are the noise source. Consult the shop manual for fuse location, module location, and any information concerning special procedures for disconnecting power.

A listening test may verify alternator noise, but if an oscilloscope is available, monitor the power line feeding the affected radio. Alternator whine appears as full-wave rectified ac ripple and rectifier switching transients superimposed on the power system's dc power voltage (see **Figure 27.27**).

Alternators rely on the low impedance of the battery for filtering. Check the wiring from the alternator output to the battery for corroded contacts and loose connectors when alternator noise is a problem.

Receivers may allow conducted harness noise to enter the RF, IF or audio sections (usually through the power leads), and interfere with desired signals. Check whether the

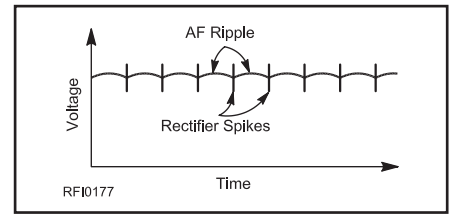

**Figure 27.27 — Alternator whine consists of full-wave rectified ac, along with pulses from rectifier switching, superimposed on the vehicle's dc power voltage.**

interference is still present with the receiver powered from a battery or power supply instead of from the vehicle. If the interference is no longer present when the receiver is operating from a battery or external supply, the interference is conducted via the radio power lead. Power line filters installed at the radio may resolve this problem.

## 27.9.4 Eliminating Automotive RFI

The next section includes various techniques to resolve the more common RFI problems. As a caveat, performing your own RFI work, in or out of warranty, you assume the same risks as you do when you perform any other type of automotive repair. Most state laws (and common sense) say that those who work on cars should be qualified to do so. In most cases, this means that work should be done either by a licensed dealer or automotive repair facility.

### CONDUCTED INTERFERENCE

To reduce common-mode current, impedance can be inserted in series with the wiring in the form of common-mode chokes. (See this chapter's section on Common-Mode Chokes.) Wire bundles may also be wound around large toroids for the same effect.

Mechanical considerations are important in mobile installations. A motor vehicle is subject to a lot of vibration. If a choke is installed on a wire, this vibration may cause the choke to flex the wire, which may ultimately fail. It is critical that any additional shielding and/or chokes placed on wiring have been installed by qualified personnel who have considered these factors. These must be properly secured, and sometimes cable extenders are required to implement this fix.

### RFI TO ON-BOARD CONTROL SYSTEMS

RFI to a vehicle's on-board control and electronic modules should be treated with common-mode chokes at the connection to the module. Some success has been reported by using braid or metal foil to cover a wire bundle as a shield and connecting the shield to the vehicle chassis near the affected module. Vehicle electronic units should not be modified except by trained service personnel according to the manufacturer's recommendations. The manufacturer may also have specific information available in the form of service bulletins.

### FILTERS FOR DC MOTORS

If the motor is a conventional brush- or commutator-type dc motor, the following cures shown in **Figure 27.28** are those generally used. As always, the mechanic should consult with the vehicle manufacturer. To diagnose motor noise, obtain an AM or SSB receiver to check the frequency or band of interest. Switch on the receiver, and then activate the electric motors one at a time. When a noisy motor is switched on, the background noise increases as well.

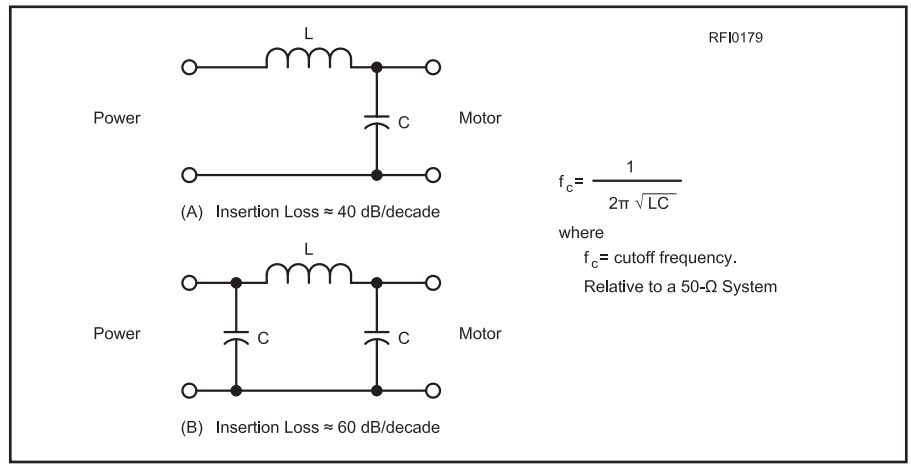

**Figure 27.28 — Filters for reducing noise from dc motors**

The pulses of current drawn by a brush-commutator motor generate broadband RFI that is similar to ignition noise. However, the receiver audio sounds more like bacon frying rather than popping. With an oscilloscope displaying receiver audio, the noise appears as a series of pulses with random space between the pulses. Such broadband noise generally has a more pronounced effect on AM receivers than on FM. Unfortunately, the pulses may affect FM receivers by increasing the "background noise level" and will reduce perceived receiver sensitivity because of the degraded signal-to-noise ratio.

### ALTERNATOR AND GENERATOR NOISE

As mentioned previously, brush-type motors employ sliding contacts which can generate noise. The resulting spark is primarily responsible for the "hash" noise associated with these devices. Hash noise appears as overlapping pulses on an oscilloscope connected to the receiver audio output. An alternator also has brushes, but they do not interrupt current. They ride on slip rings and supply a modest current, typically 4 A to the field winding. Hence, the hash noise produced by alternators is relatively minimal.

Generators use a relay regulator to control field current and thus output voltage. The voltage regulator's continuous sparking creates broadband noise pulses that do not overlap in time. They are rarely found in modern automobiles.

Alternator or generator noise may be conducted through the vehicle wiring to the power input of mobile receivers and transmitters and may then be heard in the audio output. If alternator or generator noise is suspected and an oscilloscope is not available, temporarily remove the alternator belt as a test. (This may not be possible in vehicles with a serpentine belt.)

### IGNITION NOISE

Ignition noise is created by fast-rise-time pulses of coil current discharging across air gaps (distributor and spark plug). The theoretical models (zero rise time) of such pulses are called impulse functions in the time domain. When viewed in the frequency domain, the yield is a constant spectral energy level starting nearly at 0 Hz and theoretically extending up in frequency to infinity. In practice, real ignition pulses have a finite rise time, so the spectral-energy envelope decreases above some frequency.

It turns out that noise generated by ignition sparks and fuel injector activation manifest themselves as a regular, periodic "ticking" in the receiver audio output, which varies with engine RPM. If an oscilloscope were connected to the audio output, a series of distinct, separate pulses would appear. At higher speeds it sounds somewhat musical, like alternator whine, but with a harsher note (more harmonic content).

A distinguishing feature of ignition noise is that it increases in amplitude under acceleration. This results from the increase in the required firing voltage with higher cylinder pressure. (Noise at higher frequencies may also be reproduced better by the audio circuits.) Since ignition noise is usually radiated noise, it should disappear when the antenna element is disconnected from the antenna mount. The radiation may be from either the secondary parts of the system or it may couple from the secondary to the primary of the coil and be conducted for some distance along the primary wiring to the ignition system, then radiated from the primary wiring.

Two main methods are employed to sup-

press this noise — one involves adding an inductance, and the other involves adding a resistance — both in the secondary (high voltage) wiring. This is shown in **Figure 27.29**. The addition of these elements does not have a measurable effect on the engine operation, because the time constants involved in the combustion process are much longer than those associated with the suppression components. (Note that modifying your vehicle's ignition system may be considered as tampering with your vehicle's emission control system and may affect your warranty coverage — work with your dealer or limit your efforts to changing spark plug wires or possibly shielding them.)

The resistance method suppresses RFI by dissipating energy that would have been radiated and/or conducted. Even though the amount of energy dissipated is small, it is still enough to cause interference to sensitive amateur installations. The other method uses inductance and even though the energy is not dissipated, suppression occurs because the inductor will store the pulse energy for a short time. It then releases it into the ignition burn event, which is a low impedance path, reducing the RFI.

For traditional "Kettering" inductive discharge ignition systems, a value of about 5 kΩ impedance (either real and/or reactive) in the spark plug circuit provides effective suppression and, with this value, there is no detectable engine operation degradation. (Capacitor discharge systems, in comparison, are required to have very low impedance on the order of tens of ohms in order to not reduce spark energy, so they are not tolerant of series impedance). Most spark plug resistances are designed to operate with several kV across the plug gap, so a low-voltage ohmmeter may not give proper resistance measurement results.

The term "resistor wire" is somewhat misleading. High-voltage ignition wires usually contain both resistance and inductance. The resistance is usually built into suppressor spark plugs and wires, while there is some inductance and resistance in wires, rotors and connectors. The elements can be either distributed or lumped, depending on the brand, and each technique has its own merit. A side benefit of resistance in the spark plug is reduced electrode wear.

### COIL-ON-PLUG IGNITION NOISE

Many newer spark-ignition systems incorporate a "coil on plug" (COP) or "coil near plug" (CNP) approach. There are advantages to this from an engine operation standpoint, and this approach may actually reduce some of the traditional sources of ignition system RFI. This is because of the very short secondary wires that are employed (or perhaps there are no wires — the coil is directly attached to the spark plug). This reduces the likelihood of coupling from the secondary circuit to other wires or vehicle/engine conductive structures.

There will always be some amount of energy from the spark event that will be conducted along the lowest impedance path. It may mean that the energy that would have been in the secondary circuit will be coupled back on the primary wiring harness attached to the coils. This means that the problem may go from a radiated to a conducted phenomenon.

The fix for this in some cases may actually be easier or harder than one might think. Two approaches that have been used with success are ferrite cores and bypass capacitors.

Ferrite cores are recommended as the first choice, since they require no electrical modification to the vehicle. Ferrite clamp-on split cores are added to the 12-V primary harness attached to the coils. Depending on the frequency of the noise and selection of the ferrite material, there can be significant improvement (as much as 10 dB). Key to optimizing the amount of suppression is to determine where the noise "peaks" and selecting the correct ferrite material for that frequency range (see this chapter's section Using Ferrite for RFI Suppression).

The second method is to add a bypass capacitor between the primary wire of the 12-V coil and ground in the harness near the coil assemblies (there may be 2, 3 or 4 coils). This must be done carefully because it could affect the functionality of the ignition system and — perhaps most importantly — may void the vehicle warranty. This "bypass" capacitor performs the same function that bypass capacitors in any other application perform — separating the noise from the intended signal/power.

## 27.9.5 Electric and Hybrid-Electric Vehicles

Electric vehicles (EV) and hybrid-electric vehicles (HEV) are quickly becoming a practical means of transportation. EV/HEVs are advanced vehicles that pose unique challenges for amateur equipment. While EV/HEVs provide improved emissions and fuel economy, EV/HEVs utilize switched high voltage and high current to control propulsion. The switching techniques used generate RFI within much of our frequency bands — a cause for concern, particularly for HF operation.

This section is designed to enlighten vehicle owners to the challenges and to make suggestions when installing mobile amateur equipments in an EV/HEV.

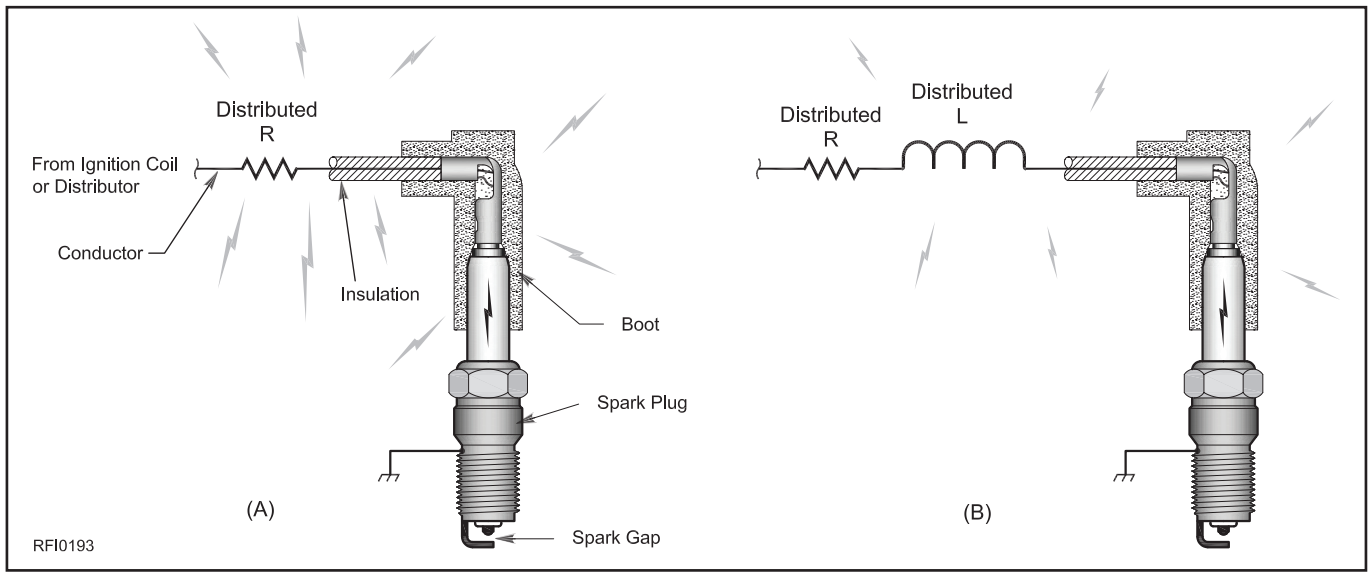

**Figure 27.29 — Ignition noise suppression methods.**

### EV AND HEV ARCHITECTURE

Most EVs and HEVs have similar electrical traction system (ETS) architectures consisting of a high voltage battery supplying energy to an inverter which controls an electric motor within a transmission connected to the drive wheels. The main difference between the two is that an HEV includes an internal combustion engine to aid in propulsion and a pure EV is strictly electrically powered.

The heart of the ETS is a device called an inverter. It simply converts dc voltage from the high voltage battery (typical voltage range from 42 to 350 V dc) to an ac waveform supplying the electric motor. This dc-to-ac conversion is performed by a matrix of six transistor switches. The switches chop the dc voltage into systematically varying pulses called pulse-width-modulation (PWM) to form an adjustable frequency and RMS voltage suitable to power electric motor.

In most cases, the ac voltage from the inverter is a three-phase waveform similar to industrial applications because three-phase motors can be smaller, more efficient, and provide greater torque than single-phase motors.

IMPORTANT — Bright orange cables connect the battery pack to the inverter and the inverter to the drive motor, transferring voltage and current to and from the inverter. Because of the non-sinusoidal waveforms being transferred, these cables are shielded and terminated at each end. Under no condition should these cables be disconnected or modified, because the high voltage system depends on a delicate balance of sensors and safety mechanisms. Possible malfunction and damage to the ETS may occur if modified.

### EV AND HEV RFI CONCERNS

The inverter uses PWM to convert dc battery voltage to an ac waveform. The phase-to-phase terminal voltage appears in **Figure 27.30** as rectangular blocks with positive and negative amplitude equal to the battery voltage. For example, a 300 V dc battery pack will provide 600 V peak-to-peak at the motor terminals. In Figure 27.30, the same terminal voltage signal is sent through a low pass filter to show how PWM forms a sinusoidal waveform. Each pulse is essentially a square wave. Harmonics from these pulses fall within most of our amateur HF bands, affecting radio performance. Because EV/HEV systems are evolving rapidly, check the ARRL's Automotive RFI web page (**www.arrl.org/automotive**) for more information.

### EV AND HEV RFI REMEDIES

Troubleshooting techniques described earlier apply in diagnosing RFI from EV/HEV systems. Limited RFI remedies are available associated to components within the ETS. Work with your dealer when you suspect the ETS as the RFI source. Do not attempt to modify or repair your ETS; the dealer's service center is most qualified to inspect and repair your EV/HEV electrical traction system.

During installation, mobile equipment power cables and antenna coaxial cables should be routed as far as possible from the bright orange cables. Common-mode chokes can decrease noise on 12-V dc power cables. Additionally, antenna placement plays a critical role in mobile equipment performance. Areas such as the top of a roof or trunk sometimes provide additional shielding.

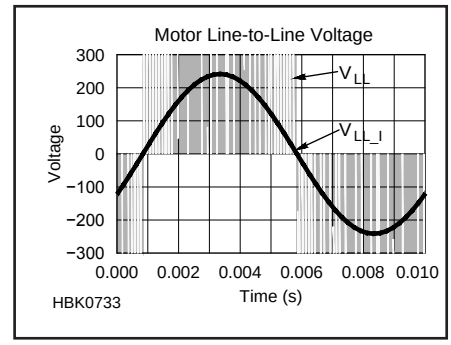

**Figure 27.30 — Phase-to-phase motor terminal voltage.**

## 27.9.6 Automotive RFI Summary

Most radio installations should result in no problems to either the vehicle systems or any issues with the transceiver. However, manufacturer, make and models differ, thus introducing challenges during amateur equipment installations.

Begin by researching your vehicle of interest and visiting the dealer. Insist on transmitting and receiving your favorite frequencies as you test drive. Request information pertaining to the manufacturer's transceiver installation guidelines. If manufacturer information is not available, follow the guidelines described earlier.

After installation, RFI problems may appear. Report you problem to the dealer, because they have access to manufacturer service bulletins which may describe a repair solution. Additional troubleshooting and remedies are also described previously to assist in successful communication.

Limited RFI remedies are available associated to components within the ETS. Work with your dealer when you suspect the ETS is the RFI source. Do not attempt to modify or repair your ETS; the dealer's service center is most qualified to inspect and repair your EV/HEV electrical traction system.

Lastly, the latest version of the *ARRL RFI Book* contains additional information on RFI in automobiles. More details are given about noise sources, troubleshooting techniques, a troubleshooting flow chart, additional filtering techniques, and information on EV/HEVs.

# 27.10 RFI Projects

Note: Additional RFI projects are included in the downloadable supplemental information accompanying this book.

## 27.10.1 *Project*: RF Sniffer

Every home is full of electrical equipment capable of emitting electromagnetic radiation to interfere with radio amateurs trying to listen to signals on the bands. This project detects the radiation that causes problems to the amateur, and the noise can be heard. This device will allow you to demonstrate the "noise" with which we have to contend.

An article by AC9PR detailing the entire construction process, including an improved RF pickup coil, is available in the downloadable supplemental information.

**Table 27.4**
**Components List**

| *Resistors* | *Value* |
|---|---|
| R1 | 1 kΩ |
| R2, R6 | 100 Ω |
| R3, R4 | 47 kΩ |
| R5 | 100 kΩ |
| R7 | 10 Ω |
| R8 | 10 kΩ, with switch |
| *Capacitors* | *Value* |
| C1, C6 | 4.7 µF, 16 V electrolytic |
| C2, C5 | 0.01 µF |
| C3, C4 | 22 µF, 16 V electrolytic |
| C7 | 0.047 µF |
| C8 | 10 µF, 16 V electrolytic |
| C9, C11 | 330 µF, 16 V electrolytic |
| C10 | 0.1 µF |
| *Semiconductors* | |
| U1 | LM741 |
| U2 | LM386 |
| *Additional Items* | |
| LS1 | Small 8-Ω loudspeaker |
| Perforated board | |
| 9 V battery and clip | |
| 3.5 mm mono-jack socket | |
| Case | |
| Telephone pick-up coil | |

### CONSTRUCTION

The circuit (**Figure 27.31**) uses a telephone pick-up coil as a detector, the output of which is fed into a LM741 IC preamplifier, followed by a LM386 IC power amplifier. See **Table 27.4** for the complete component list. An article by AC9PR detailing the entire construction process including an improved RF pickup coil is available in the downloadable supplemental information.

The project is built on a perforated board (**Figure 27.32**), with the component leads pushed through the holes and joined with hook-up wire underneath. There is a wire running around the perimeter of the board to form an earth bus.

Build from the loudspeaker backwards to R8, apply power and touch the wiper of R8. If everything is OK you should hear a loud buzz from the speaker. Too much gain may cause a feedback howl, in which case you will need to adjust R8 to reduce the gain. Complete the rest of the wiring and test with a finger on the input, which should produce a click and a buzz. The pick-up coil comes with a lead and 3.5 mm jack, so you will need a suitable socket.

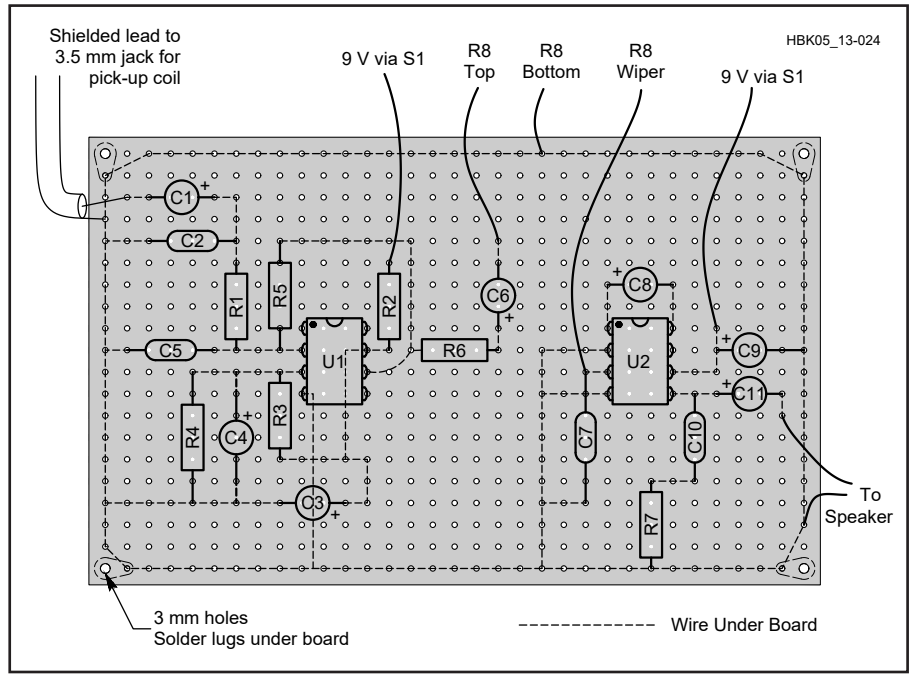

**Figure 27.32 — The project is built on perforated board with point-to-point wiring underneath.**

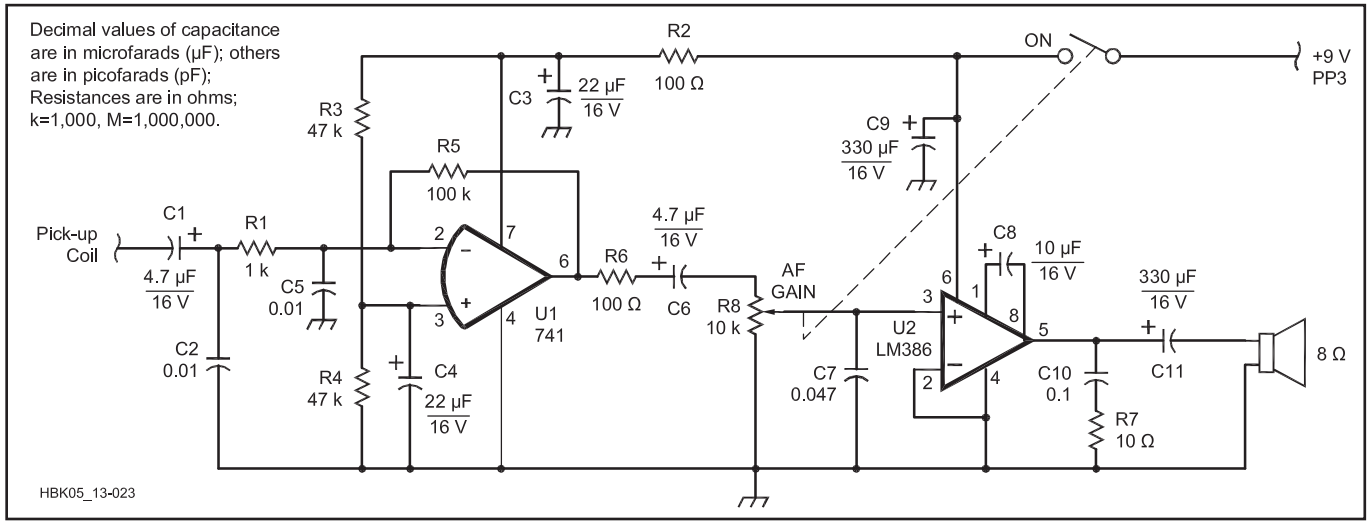

**Figure 27.31 — The detector works by receiving stray radiation on a telephone pick-up coil and amplifying it to loudspeaker level.**

### RELATIVE NOISES

Place a high-impedance meter set to a low-ac-voltage range across the speaker leads to give a comparative readout between different items of equipment in the home. Sample readings are shown in **Table 27.5**.

**Table 27.5**
**Readings (pick-up coil near household items)**

| | | | |
|---|---|---|---|
| 29-MHz oscilloscope | 0.56 V | Old TV | 1.2 V |
| Old computer CRT monitor | 0.86 V | New TV | 0.4 V |
| Old computer with plastic case | 1.53 V | Plastic-cased hairdryer | 4.6 V |
| New computer CRT monitor | 0.45 V | Vacuum cleaner | 3.6 V |
| New tower PC with metal case | 0.15 V | Drill | 4.9 V |

# 27.11 RFI Glossary

***Balanced circuit*** — A circuit whose two conductors have equal impedance to a common reference, such as a reference plane or circuit common.

***Bond*** — (noun) A low-impedance, mechanically robust, electrical connection.

***Common-mode*** — In a group of conductors, such as multi-conductor cable, voltage or current that is present with the same amplitude, phase and polarity on all conductors in a group, such as multi-conductor cable. AC current flowing on the outside of a coaxial cable shield is also considered to be common-mode current..

***Conducted RFI*** — RFI received via a conducting path.

***Coupled RFI*** — RFI received via inductive or capacitive coupling between conductors.

***Differential mode*** — A signal that that is exists and is transmitted as a voltage *between* two conductors of a cable. At any instant, signal current on one conductor is equal to but of the opposite polarity to the current on the other conductor. Ordinary connections between equipment in systems are differential mode signals.

***Disturbance*** — The improper operation of a device as a result of interference.

***Electric field*** — The field present between two or more conductive objects as a result of potential difference (voltage) between those objects.

***Electromagnetic field*** — The combination of a magnetic field and electric field in which the fields are directly related to each other, are at right angles to each other, and move through space as radio waves in a direction that is mutually perpendicular to both fields. An electrical conductor designed to produce electromagnetic fields when carrying an RF current is called an antenna.

***Equipment ground*** — The connection of all exposed parts of electrical equipment to earth, or to a body that serves in place of earth.

***Fundamental overload*** — 1. (Receiver Performance) Interference to a receiver caused by a signal at its input whose amplitude exceeds the maximum signal-handling capabilities of one or more receiver stages. 2. (RF interference) — Any disruption to the function of any RFI victim caused by the fundamental component of a transmitted signal or intended in-band output of a transmitter.

***Ground*** — 1. A low impedance electrical connection to earth, or to a body that serves in place of earth. 2. A common signal connection in an electrical circuit.

***Immunity*** — The ability of a device to function properly in the presence of unwanted electromagnetic energy. (After Ott, section 1.3)

***Intentional radiator*** — A device that uses radio waves to transmit information by antenna action. A radio transmitter, with its associated antenna, is an intentional radiator.

***Interference*** — 1. Disruption of a device's normal function as a result of an electromagnetic field, voltage, or current. 2. Disruption by a signal or noise of a receiver's ability to acquire and process a desired signal.

***Magnetic field*** — The field produced by a permanent magnet or current flow through a conductor.

***Path*** — The route by which electromagnetic energy is transferred from a transmitter to a receiver or from a source to a victim.

***Radiated RFI*** — RFI received through radiation.

***Shielding*** — A conductive barrier or enclosure interposed between two regions of space with the intent of preventing a field in one region from reaching the other region.

***Source*** — A device that produces an electromagnetic, electric, or magnetic field, voltage, or current. If RFI is the result, the source is an *RFI source*.

***Spurious emission*** — An emission outside the bandwidth needed for transmission of the mode being employed, the level of which may be reduced without reducing the quality of information being transmitted. Spurious emissions are most commonly the products of distortion (harmonics, intermodulation), of circuit instability (oscillation, including RF feedback), or of digital transmission with excessively fast rise times (including key clicks). Phase noise, such as that produced by a frequency synthesizer is also a spurious emission.

***Susceptibility*** — The capability of a device to respond to unwanted electromagnetic energy. (After Ott, section 1.3)

***System ground*** — A bond between one current-carrying conductor of the power system and earth.

***Unintentional radiator*** — A device that produces RF as part of its normal operation but does not intentionally radiate it.

***Victim*** — A device that receives interference from a *source*.

Chapter 28

# Safe Practices

Previously named "Safety," this chapter focuses on safe practices to avoid common hazards associated with ac electrical power, antennas and towers, and RF exposure. The first section, updated from material originally written by Jim Lux, W6RMK, and updated by Ward Silver, NØAX, details electrical safety, grounding, bonding, and related issues in the station. The following section on antenna and tower safety was updated by Jim Idelson, K1IR. Finally, the ARRL RF Safety Committee explains good amateur practices, standards, and FCC regulations as they apply to RF exposure, including recent updates to station evaluation requirements.

## Safety First — Always

We need to learn as much as possible about what could go wrong so we can avoid factors that might result in accidents. Amateur Radio activities are not inherently hazardous, but like many things in modern life, it pays to be informed. Stated another way, while we long to be creative and innovative, there is still the need to act responsibly. Safety begins with our attitude. Make it a habit to plan work carefully. Don't be the one to say, "I didn't think it could happen to me."

Having a good attitude about safety is not enough, however. We must be knowledgeable about common safety guidelines and follow them faithfully. Safety guidelines cannot possibly cover all situations, but if we approach each task with a measure of common sense, we should be able to work safely.

Involve your family in Amateur Radio. Having other people close by is always beneficial in the event that you need immediate assistance. Take the valuable step of showing family members how to turn off the electrical power to your equipment safely. Additionally, cardiopulmonary resuscitation (CPR) training can save lives in the event of electrical shock. Classes are offered in most communities. Take the time to plan with your family members exactly what action should be taken in the event of an emergency, such as electrical shock, equipment fire or power outage. Practice your plan!

## 28.1 Electrical Safety

The standard power available from commercial mains in the United States for residential service is 120/240-V ac. The "primary" voltages that feed transformers in our neighborhoods may range from 1300 to more than 10,000 V. Generally, the responsibility for maintaining the power distribution system belongs to a utility company, electric cooperative or city. The "ownership" of conductors usually transfers from the electric utility supplier to the homeowner where the power connects to the meter or weather head. If you are unsure of where the division of responsibility falls in your community, a call to your electrical utility will provide the answer. **Figure 28.1** shows the typical division of responsibility between the utility company and the homeowner. This section is concerned more with wiring practices in the shack, as opposed to within the equipment in the shack.

There are two facets to success with electrical power: safety and performance. Since we are not professionals, we need to pursue safety first and consult professionals for alternative solutions if performance is unacceptable. The ARRL's Volunteer Consulting Engineers program involves professional engineers who may be able to provide advice or direction on difficult problems.

### 28.1.1 Station Concerns

There never seem to be enough power outlets in your shack. A good solution for small scale power distribution is a switched power strip with multiple outlets. The strip should be listed by a nationally recognized testing laboratory (NRTL) such as Underwriters Lab, UL, and should incorporate a circuit breaker. See the sidebars "What Does UL Listing Mean?" and "How Safe are Outlet Strips?" for warnings about poor quality products. It is poor practice to "daisy-chain" several power strips and may actually be a code violation. If you need more outlets than are available on a strip, have additional wall outlets installed.

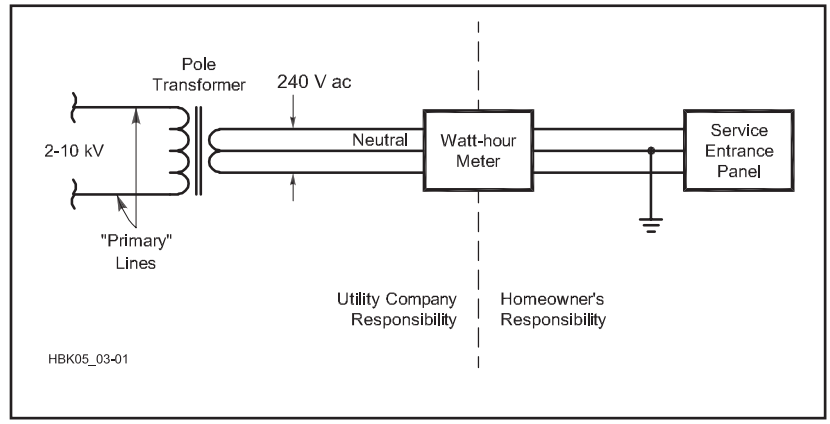

**Figure 28.1 — Typical division of responsibility for maintenance of electrical power conductors and equipment. The meter is supplied by the utility company.**

## What Does UL Listing Mean?

UL is one of several nationally recognized testing laboratories (NRTLs), and probably the most well known. Listing *does not* mean what most consumers expect it to mean! More often than not the listing *does not* relate to the performance of the listed product. The listing simply indicates that a sample of the device meets certain manufacturers' construction criteria. Similar devices from the same or different manufacturers may differ significantly in overall construction and performance even though all are investigated and listed against the same UL product category. There is also a difference between a listed device and a listed component.

Many local laws and regulations, as well as the National Electrical Code, require that equipment and components used in electrical installations be listed by a NRTL. Some jurisdictions (Los Angeles County) require that any electrical equipment sold to consumers be listed.

The consumer must also be aware of the fine distinctions in advertising between a device or component that is advertised as "listed" or "designed to meet" or "meets." The latter two may not actually have been tested, or if tested, may have been tested by the manufacturer, and not an independent body.

It's also important to know that in some cases UL (and other standards organizations) only publish a standardized test procedure, but don't necessarily list or test the devices. Many standards also define varying levels of compliance, so knowing that your device meets some part of the standard may not be enough to know whether it meets *your* particular needs.

## Grounding and Bonding for the Radio Amateur

There is so much information about ac safety, lightning protection, and dealing with RF in the station that it can be difficult to understand it all. While this chapter is a helpful summary, it is still just a summary. To help hams setting up a station for the first time or trying to improve an existing station, the ARRL has published *Grounding and Bonding for the Radio Amateur*. Along with its website (**www.arrl.org/grounding-and-bonding-for-the-radio-amateur**) the book collects information about these important practices into one reference.

## How Safe Are Outlet Strips?

The switch in outlet strips is generally *not* rated for repetitive *load break* duty. Early failure and fire hazard may result from using these devices to switch heavy loads on and off. Misapplications are common (another bit of bad technique that has evolved from the use of personal computers), and manufacturers are all too willing to accommodate the market with marginal products. A lockable disconnect switch or circuit breaker is a better and safer station master switch.

Older power strips not complying with current standards can also be a safety hazard. MOVs in these older strips that are subjected to repeated transients can fail and cause a fire hazard, especially in outlet strips with plastic enclosures. Power strips made after 2009 that comply with UL standards are safe to use.

Whether you add new outlets or use power strips, be sure not to overload the circuit. National and local codes set permissible branch capacities according to a rather complex process. Here's a safe rule of thumb: consider adding a new circuit if the total load is more than 80% of the circuit breaker or fuse rating. (This assumes that the fuse or breaker is correct. If you have any doubts, have an electrician check it.)

### 28.1.2. Do-It-Yourself Wiring

Amateurs sometimes "rewire" parts of their homes to accommodate their hobby. Most local codes *do* allow for modification of wiring (by building owners), so long as the electrical codes are met. Before making changes to your wiring, it would be wise to determine what rules apply and what agency has the authority to enforce them. This is called the *authority having jurisdiction* (AHJ) and it varies from location to location. Also see the following section on the National Electrical Code.

Generally, the building owner must obtain an electrical permit before beginning changes or additions to permanent wiring. Some jobs may require drawings of planned work. Often the permit fee pays for an inspector to review the work. Considering the risk of injury or fire if critical mistakes are left uncorrected, a permit and inspection are well worth the effort. *Don't take chances* — seek assistance from the building officials or an experienced electrician if you have *any* questions or doubts about proper wiring techniques.

*Ordinary 120-V circuits are the most common source of fatal electrical accidents*. Line voltage wiring must use an approved cable, be properly installed in conduit and junction boxes, within a chassis with a cover or lid, or other means described in the electrical code. Remember that high-current, low-voltage power sources, such as car batteries and high-current power supplies, can be just as dangerous as high-voltage sources, from melting metal, sparks and short circuits.

*Never work on electrical wiring with the conductors energized!* Switch off the circuit breaker or remove the fuse and take positive steps to ensure that others do not restore the power while you are working, such as using a circuit-breaker lockout. (**Figure 28.2** illustrates one way to ensure that power will be off until you want it turned on.) Check the circuit with an ac voltmeter to be sure that it is "dead" *each time you begin work*.

*Before* restoring power, check the wiring with an ohmmeter: From the installed outlet, there should be good continuity between the neutral conductor (white wire, "silver" screw) and the grounding conductor (green or bare wire, green screw). An ohmmeter should indicate a closed circuit between the conductors. (In the power line, high voltage world, line workers apply a shorting jumper before starting work so if the power does get reapplied, the safety jumper takes the hit.)

With all other loads removed from the circuit (by turning off or unplugging them), an ohmmeter should indicate an *open* circuit between the hot wire and either of the other two conductors. There should be no continuity between the hot conductor (black wire, "brass" screw) and the grounding conductor or the neutral conductor.

**Figure 28.2 — If the switch box feeding power to your shack is equipped with a lock-out hole, use it. With a lock through the hole on the box, the power cannot be accidentally turned back on. [Photo courtesy of American ED-CO]**

Commercially available plug-in testers are a convenient way to test regular three-wire receptacles, but can't distinguish between the neutral and ground being reversed.

It is wise to have an up-to-date reference guide to wiring practices. These guides may be available from home improvement stores and electrical supply houses. As of early 2017, one widely available book is the *Black & Decker Complete Guide to Wiring, 6th edition*. The book is inexpensive and includes many step-by-step instructions for basic and intermediate wiring projects.

### 28.1.3 National Electrical Code (NEC)

Fortunately, much has been learned about how to harness electrical energy safely. This collective experience has been codified into the *National Electrical Code*, or *NEC*, simply known as "the code." The code details safety requirements for many kinds of electrical installations. Compliance with the NEC provides an installation that is *essentially* free from hazard, but not necessarily efficient, convenient or adequate for good service (paraphrased from NEC Article 90-1a and b). While the NEC is national in nature and sees wide application, it is not universal.

Local building authorities set the codes for their area of jurisdiction. They often incorporate the NEC in some form, while considering local issues. For example, Washington State specifically exempts telephone, telegraph, radio and television wires and equipment from conformance to electrical codes, rules and regulations. However, some local jurisdictions (city, county and so on) do impose a higher level of installation criteria, including some of the requirements exempted by the state.

Code interpretation is a complex subject, and untrained individuals should steer clear of the NEC itself. The NEC is not written to be understood by do-it-yourselfers, and one typically has to look in several places to find *all* the requirements. (For instance, Articles 810, 250, *and* 100 all contain things applicable to typical Amateur Radio installations.) The *NEC Handbook* is a version of the code with additional drawings and discussion. It explains the requirements of the code and how to satisfy those requirements. Written for electricians, even the *NEC Handbook* may be difficult for the non-electrician to understand completely. You may wish to contact local sources of information about code compliance and acceptable practices such as local building officials or inspectors, electrical engineers, and practicing electricians. The NEC and the *NEC Handbook* are available from local libraries.

The internet has a lot of information about electrical safety, the electrical code, and wiring practices, but you need to be careful to make sure the information you are using is current and not out of date. The ARRL Volunteer Consulting Engineer (VCE) program can help you find a professional who understands the amateur radio world, as well as the regulatory environment. There are also a variety of websites with useful information (such as **www.mikeholt.com** ), but you need to be aware that advice may be specific to a particular installation or jurisdiction and not applicable for yours. With that understanding, let's look at a few NEC requirements for radio installations.

#### HOMEBREW AND "THE CODE"

In many cases, there are now legal requirements that electrical equipment have been listed by an NRTL, such as Underwriter Laboratories. This raises an issue for hams and homebrew gear, since it's unlikely you would take your latest project down to a test lab and pay them to evaluate it for safety.

For equipment that is not permanently installed, there's not much of an issue with homebrew, as far as the code goes, because the code doesn't deal with what's inside the equipment. For a lot of low voltage equipment, the code rules are fairly easy to meet, as well, as long as the equipment is supplied by a listed power source of the appropriate type.

The problem arises with permanent installations, where the scope of the code and local regulations is ever increasing. Such things as solar panel installations, standby generators, personal computers and home LANs all have received increased attention in local codes.

### 28.1.4 Station Power

Amateur Radio stations generally require a 120-V ac power source, which is then converted to the proper ac or dc levels required for the station equipment. In residential systems voltages from 110 V through 125 V are treated equivalently, as are those from 220 V through 250 V. Amateurs setting up a station in a light industrial or office environment may encounter 208 V line voltage. Most power supplies operate over these ranges, but it's a good idea to measure the voltage range at your station. (The measured voltage usually varies by hour, day, season and location.) Power supply application and use are covered in the **Power Sources** chapter.

Modern solid state rigs often operate from dc power, provided by a suitable dc power supply, perhaps including battery backups. Sometimes, the dc power supply is part of the rig (as in a 50-V power supply for a solid-state linear). Other times, your shack might have a 12-V (13.8 V) bus that supplies many devices. Just because it's low voltage doesn't mean that there aren't aspects of the system that raise safety concerns. A 15-A, 12-V power

## About the National Electrical Code

***Exactly how does the National Electrical Code become a requirement? How is it enforced?***

States, cities and, political subdivisions (jurisdictions) have the responsibility to act for the safety and welfare of the public. To address the safety and welfare of everyone, specific codes may be adopted by these jurisdictions. Because the technology for the development of general construction, mechanical, and electrical codes is beyond the scope of most jurisdictions, existing codes are adopted. These codes may be adopted by reference as they stand, or they may be amended and incorporated into local laws and ordinances. Many jurisdictions include some form of permit and accompanying inspection process within the local laws and ordinances. These codes may include, but are not limited to, the International Building Code (IBC), International Residential Code (IRC), and the National Electrical Code (NEC). For electrical issues, the National Electrical Code has been adopted by every state and most local jurisdictions within the United States. Officials within these jurisdictions will serve as "the authority having jurisdiction" (AHJ) and interpret the provisions of these Codes as they apply to specific cases.

Building codes differ from planning or zoning regulations: Building codes are directed only at safety, fire and health issues. Zoning regulations often are aimed at preservation of property values and aesthetics.

The NEC is part of a series of reference codes published by the National Fire Protection Association, a nonprofit organization. Published codes are regularly kept up-to-date and are developed by a series of technical committees whose makeup represents a wide consensus of opinion. The NEC is updated every three years. It's important to know which version of the code your local jurisdiction uses, since it's not unusual to have the city require compliance to an older version of the code. Fortunately, the NEC is usually backward compatible: that is, if you're compliant to the 2008 code, you're probably also compliant to the 1999 code.

***Do I have to update my electrical wiring as code requirements are updated or changed?***

Generally, no. Codes are typically applied for new construction and for renovating existing structures. Room additions, for example, might not directly trigger upgrades in the existing service panel unless the panel was determined to be inadequate. However, the wiring of the new addition would be expected to meet current codes. Prudent homeowners, however, may want to add safety features for their own value. Many homeowners, for example, have added GFCI protection to bathroom and outdoor convenience outlets.

## International Power Standards

The power grid of the United States and Canada uses a frequency of 60 Hz and the voltage at ac power outlets is 120 V. This is also the case in other North American countries. If you travel, though, you'll encounter 220 V and 50 Hz with quite an array of plugs and sockets and color codes. If you are planning on taking amateur radio equipment with you on a vacation or DXpedition, you'll need to be prepared with the proper adapters and/or transformers to operate your equipment.

A table of international voltage and frequencies is provided with the downloadable supplemental content, along with a figure showing the most common plug and socket configurations.

supply can start a fire as easily as a 15-A, 120-V branch circuit.

### 28.1.5 Connecting and Disconnecting Power

Something that is sometimes overlooked is that you need to have a way to safely disconnect all power to everything in the shack. This includes not only the ac power, but also battery banks, solar panels, and uninterruptible power supplies (UPS). Most hams won't have the luxury of a dedicated room with a dedicated power feed and the "big red switch" on the wall, so you'll have several switches and cords that would need to be disconnected.

The realities of today's shacks, with computers, multiple wall transformers ("wall-warts"), network interfaces and the radio equipment itself makes this tricky to do. One convenient means is a switched outlet strip, as used for computer equipment, if you have a limited number of devices. If you need more switched outlets, you can control multiple low-voltage controlled switched outlets from a common source. Or you can build or buy a portable power distribution box similar to those used on construction sites or stage sets; they are basically a portable subpanel with individual circuit breakers (or GFCIs, discussed later) for each receptacle, and fed by a suitable cord or extension cord. No matter what scheme you use, however, it's important that it be labeled so that someone else will know what to do to turn off the power.

#### AC LINE POWER

If your station is located in a room with electrical outlets, you're in luck. If your station is located in the basement, an attic or other area without a convenient 120-V source, you may need to have a new line run to your operating position.

Stations with high-power amplifiers should have a 240-V ac power source in addition to the 120-V supply. Some amplifiers may be powered from 120 V, but they require current levels that may exceed the limits of standard house wiring. To avoid overloading the circuit and to reduce household light dimming or blinking when the amplifier is in use, and for the best possible voltage regulation in the equipment, it is advisable to install a separate 240 or 120-V line with an appropriate current rating if you use an amplifier.

The usual circuits feeding household outlets are rated at 15 or 20 A., This may or may not be enough current to power your station. To determine how much current your station requires, check the VA (volt-amp) ratings for each piece of gear. (See the **Electrical Fundamentals** chapter for a discussion of VA.) Usually, the manufacturer will specify the required current at 120 V; if the power consumption is rated in watts, divide that rating by 120 V to get amperes. Modern switching power supplies draw more current as the line voltage drops, so if your line voltage is markedly lower than 120 V, you need to take that into account.

Note that the code requires you to use the "nameplate" current, even if you've measured the actual current, and it's less. If the total current required is near 80% of the circuit's rating (12 A on a 15-A circuit or 16 A on a 20-A circuit), you need to install another circuit. Keep in mind that other rooms may be powered from the same branch of the electrical system, so the power consumption of any equipment connected to other outlets on the branch must be taken into account. If you would like to measure just how much power your equipment consumes, the inexpensive Kill-A-Watt meters by P3 International (**www.p3international.com**) measure volts, amps, VA and power factor.

If you decide to install a separate 120-V line or a 240-V line, consult the local requirements as discussed earlier. In some areas, a licensed electrician must perform this work. Others may require a special building permit. Even if you are allowed to do the work yourself, it might need inspection by a licensed electrician. Go through the system and get the necessary permits and inspections! Faulty wiring can destroy your possessions and take away your loved ones. Many fire insurance policies are void if there is unapproved wiring in the structure.

If you decide to do the job yourself, work closely with local building officials. Most home-improvement centers sell books to guide do-it-yourself wiring projects. If you have any doubts about doing the work yourself, get a licensed electrician to do the installation.

#### THREE-WIRE 120-V POWER CORDS

Most metal-cased electrical tools and appliances are equipped with three-conductor power cords. Two of the conductors carry power to the device, while the third conductor is connected to the case, enclosure, or frame. **Figure 28.3** shows two commonly

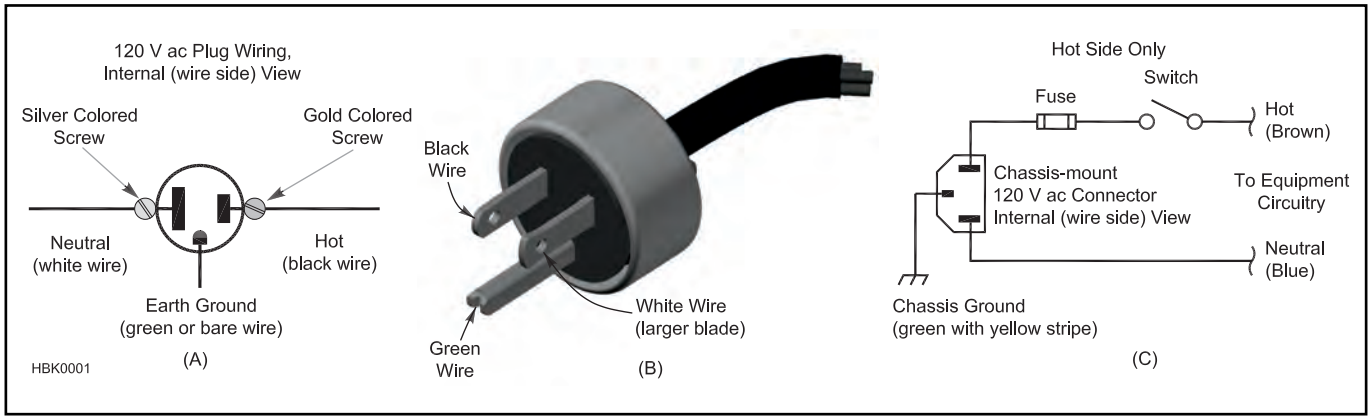

**Figure 28.3 — 120 V ac plug wiring as viewed from the wire side (A) and viewed from the blade side (B). Wiring for an IEC type chassis connector is shown at C.**

used connectors. (See the **Component Data and References** chapter for a more comprehensive drawing of ac plugs and receptacles.)

When both plug and receptacle are properly wired, the three-contact polarized plug bonds the equipment to the system ground. If an internal short from line to case occurs, the "ground" pin carries the fault current and hopefully has a low enough impedance to trip the branch circuit breaker or blow the fuse in the device. A second reason for grounding the case is to reduce the possibility of shock for a user simultaneously connected to ground and the device. In modern practice, however, shock prevention is often done with GFCI circuit breakers as described below. These devices trip at a much lower level and are more reliable. Most commercially manufactured test equipment and ac-operated amateur equipment is supplied with three-wire cords.

It's a good idea to check for continuity from case to ground pin, particularly on used equipment, where the ground connection might have been broken or modified by the previous owner. If there is no continuity, have the equipment repaired before use.

Use such equipment only with properly installed three-wire outlets. If your house does not have such outlets, either consult a local electrician to learn about safe alternatives or have a professional review information you might obtain from online or other sources.

Equipment with plastic cases is considered "double insulated" and fed with a two-wire cord. Such equipment is safe because both conductors are insulated from the user by two layers. Nonetheless, there is still a hazard if, say, a double insulated drill were used to drill an improperly grounded case of a transmitter that was still plugged in. Remember, all insulation is prey to age, damage and wear that may erode its initial protection.

**Table 28.1**
**Traditional Divisions Among the Classes of Circuits**

| *Class* | *Power* | *Notes* |
|---|---|---|
| **Class 1** | | |
| Power Limited | <30V, <1000VA | Transformer protected per Article 450. If not transformer, other overcurrent and fault protection requirements apply |
| Remote Control and Signaling | <600V | No limit on VA<br>Transformers protected as defined in Article 450 |
| **Class 2** | Power supply <100VA<br>Voltage <30V | |
| **Class 3** | Power supply <100VA<br>Voltage <100V | |

### TRANSFER SWITCHES AND GENERATORS

More hams are adding standby generators and using alternate power sources such as solar panels or wind turbines, not as standalone systems like at Field Day, but interconnected with their home electrical system. These present some potential safety problems, such as preventing the local generator from "backfeeding" the utility's system during a power failure, and the fact that a solar panel puts out power whenever there is light falling on it.

For generators, the recommended approach is to use a *transfer switch*, which is a multipole switch that connects a selection of the house's circuits to the generator, rather than the utility power. The NEC and local regulations should be consulted for transfer switch selection and connection. The required wiring practices for permanently installed (stationary) generators are different from those for portable generators. Some issues that need to be considered are whether the neutral should be switched (many transfer switches do not switch the neutral, only the hot wire), and how the generator chassis is bonded to the building's grounding/bonding system. Most proper transfer switches are of the ON-OFF-ON configuration, with a mechanical interlock that prevents directly switching from one source to the other in a single operation.

The most dangerous thing to do with a generator is to use a so-called "suicide cord" with a male plug at each end: one end plugged into the generator's output receptacle and the other plugged into a convenient receptacle in the home. This is frequently illegal and at any rate should be avoided because of the inherent danger of having exposed, live contacts and the ease of overloading the circuit being fed.

Back-feeding your home's power panel should *never* be done unless the main breakers are in the OFF position or preferably removed. If your home's circuit-breaker panel does not have main breakers that can disconnect the external power line, *do not* use this technique to connect your generator to the home's wiring. Your generator is likely to be damaged when power is restored, and backfeeding also endangers power utility workers. Connect appliances to the generator directly with extension cords.

## 28.1.6 Ground-Fault and Arc-Fault Circuit Interrupters

GFCIs are devices that can be used with common 120 V household circuits to reduce the chance of electrocution when the path of current flow leaves the branch circuit (say, through a person's body to another branch or ground). An AFCI is similar in that it monitors current to watch for a fault condition. Instead of current imbalances, the AFCI detects patterns of current that indicate an arc — one of the leading causes of home fires. The AFCI is not supposed to trip because of "normal" arcs that occur when a switch is opened or a plug is removed.

The NEC requires GFCI outlets in all wet or

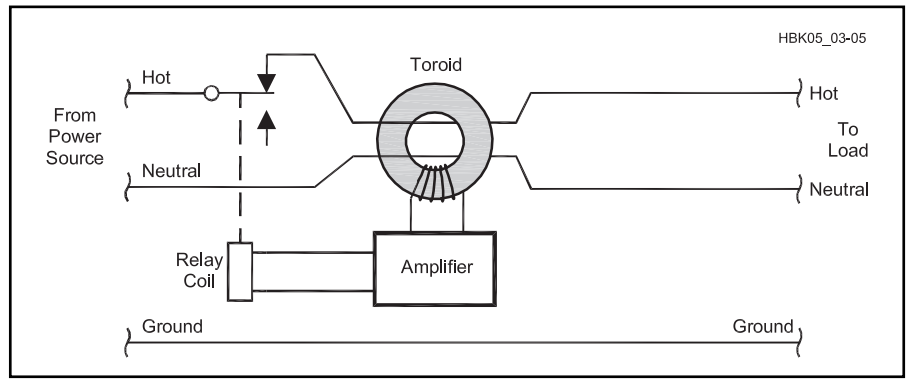

**Figure 28.4 — Simplified diagram of a 120-V ac ground fault circuit interrupter (GFCI). When a stray current flows from the load (or outlet) side to ground, the current through the toroid becomes unbalanced allowing detection, amplification and relay actuation to immediately cut off power to the load (and to the stray path!) GFCI units require a manual reset after tripping. GFCIs are required in wet locations (near kitchen sinks, in garages, in outdoor circuits and for construction work.) They are available as portable units or combined with over-current circuit breakers for installation in entrance panels.**

potentially wet locations, such as bathrooms, kitchens, and any outdoor outlet with ground-level access, garages and unfinished basements. AFCI protection is required for all circuits that supply bedrooms. Any area with bare concrete floors or concrete masonry walls should be GFCI equipped. GFCIs are available as portable units, duplex outlets and as individual circuit breakers. Some early units may have been sensitive to RF radiation but this problem appears to have been solved. Ham radio shacks in potentially wet areas (basements, out buildings) should be GFCI equipped. **Figure 28.4** is a simplified diagram of a GFCI.

Older equipment with capacitors in the 0.01 µF to 0.1 µF range connected between line inputs and chassis as an EMI filter (or that has been modified with bypass capacitors) will often cause a GFCI to trip, because of the leakage current through the capacitor. The must-trip current is 5 mA, but many GFCIs trip at lower levels. At 60 Hz, a 0.01 µF capacitor has an impedance of about 265 kΩ, so there could be a leakage current of about 0.5 mA from the 120 V line. If you had several pieces of equipment with such capacitors, the leakage current will trip the GFCI.

Some early GFCI breakers were susceptible to RFI but as the technology has improved, fewer and fewer such reports have been received. While it is possible to add filtering or RF suppression to the breaker wiring, a simpler and less expensive solution is to simply replace the GFCI breaker with a new unit less susceptible to RF. Reports have not yet been received on AFCI products. For more information on RFI and GFCI/AFCI devices, check the ARRL web page **www.arrl.org/gfci-devices**.

## 28.1.7 Low-Voltage Wiring

Many ham shacks use low-voltage control wiring for rotators or antenna relays. The electrical code isn't consistent in what it calls low voltage, but a guideline is "less than 50 V." Article 725 of the code contains most of the rules for low voltage/low power remote control and signaling, which is what hams are typically doing. These circuits are divided into three classes, with Class 1 being further subdivided, as shown in **Table 28.1**. There used to be code rules defining the classes in terms of power and voltage, but these days, the code is written so that the class of the circuit is defined by the power source, which has to be listed and labeled with the class. That is, if you have something powered by a wall transformer that is listed and labeled as Class 2, the circuit is Class 2.

A typical example of a Class 1 Power Limited circuit that you might find in your home is 12 V low-voltage garden lighting or halogen lightning systems. A lot of amateur homebrew gear probably is also in this class, although because it's not made with "listed" components, it technically doesn't qualify. The other Class 1 would apply to a circuit using an isolation transformer of some sort.

Class 2 is very common: doorbells, network wiring, thermostats, and so on are almost all Class 2. To be Class 2, the circuit must be powered from a listed power supply that's marked as being Class 2 with a capacity less than 100 VA. For many applications that hams encounter, this will be the familiar "wall wart" power supply. If you have a bunch of equipment that runs from dc power, and you build a dc power distribution panel with regulators to supply them from a storage battery or a big dc power supply, you're most likely not Class 2 anymore, but logically Class 1. Since your homebrew panel isn't likely to be listed, you're really not even Class 1, but something that isn't covered by the code.

A common example of a Class 3 circuit that is greater than 30 V is the 70 V audio distribution systems used in paging systems and the like. Class 3 wiring must be done with appropriately rated cable.

### WIRING PRACTICES

Low voltage cables must be separated from power circuits. Class 2 and 3 cannot be run with Class 1 low voltage cables. They can't share a cable tray or the same conduit. A more subtle point is that the 2005 code added a restriction [Article 725.56(F)] that audio cables (speakers, microphone, etc.) cannot be run in the same conduit with other Class 2 and Class 3 circuits (like network wiring).

Low voltage and remote control wiring should not be neglected from your transient suppression system. This includes putting appropriate protective devices where wiring enters and leaves a building, and consideration of the current paths to minimize loops which can pick up the field from transients (or RF from your antenna).

## 28.1.8 Grounding and Bonding

As hams we are concerned with at least four kinds of connections called "ground," even if they really aren't in the sense of connection to the Earth. These are easily confused because we call each of them "ground."

1) Electrical safety ground (equipment ground or earth connection)

2) Lightning and transient dissipation ground

3) RF voltage and current management ("RF ground")

4) Common reference potential (chassis ground or circuit common)

This section of the chapter is primarily concerned with connections for electrical or safety grounding and lightning and transient dissipation. The remaining types are covered elsewhere in chapters on circuit- and antenna-building and in station construction.

Several commercial and military standards can be used as guidebooks for grounding and bonding:

*National Electrical Code (NEC)* — This is the primary standard for residential and commercial electrical work in the United States. NEC Article 250 deals with grounding and bonding. NEC Article 810 deals with antenna installation. (See the previous section on the NEC.)

*MIL-HDBK-419A — Grounding, Bonding, and Shielding for Electronic Equipments and Facilities (Vol 1 and 2)* — This military standard applies to communication facilities and equipment installations at any frequency. It provides many useful drawings and guidelines covering ground connections and how equipment should be bonded together. It is a public-domain document and may be downloaded without charge at **www.uscg.mil/petaluma/TPF/ET_SMS/Mil-STDs/MILHDBK419.pdf**.

*R56 Standards and Guidelines for Communications Sites* — Motorola is a large vendor of communications systems, mostly for VHF/UHF/microwave applications. This standard applies primarily to equipment and facilities used at those frequencies. It is not a public domain document but may be downloaded without charge from numerous sources.

IEEE Std 1100-2005 (also known as the "Emerald Book," see the Reference listing, section 28.1.13) provides detailed information from a theoretical and practical standpoint for grounding and powering electrical equipment, including lightning protection and RF EMI/EMC concerns. It's expensive to buy, but is available through libraries.

### Grounding or Bonding?

You may notice the term "bonding" is replacing "grounding" in many instances. A primary safety concern is for whatever carries fault currents to be mechanically rugged and reasonably conductive. It's also important that the fault-carrying conductor be connected to a ground rod, but that's a different consideration. Bonding is the term to use when contact between pieces of equipment or between conductors is the primary concern. Grounding is the term to use when referring to an earth connection for electrical safety or lightning protection.

## BONDING

The definition of bonding is "to connect equipment together electrically in order to minimize the potential (voltage) difference between them." A good bonding connection must have very low impedance and approximately equal voltage everywhere along it at the frequency of interest. As amateurs know, electrical length and impedance of any type of conductor — wire, strap, braid, or sheet — varies with frequency. In addition, the amount of current flowing through the conductor can create significant voltage differences along the conductor. Because of these concerns, it is important to consider the purposes of bonding when making a bonding connection.

In general, for amateurs constructing a station, even a temporary one, it is a good practice to make bonding conductors as short as practical and as heavy as is needed to satisfy all bonding requirements. By doing so, the bonding connection will serve its purpose for all three of the primary bonding needs in your station: ac safety, lightning protection, and RF management.

## ELECTRICAL SAFETY GROUND

Power-line ground is required by building codes to ensure the safety of life and property surrounding electrical systems. The NEC requires that all grounds be bonded together; this is a very important safety feature as well as an NEC requirement.

The usual term one sees for the "third prong" or "green-wire ground" is the *electrical safety ground* or *equipment ground*. The purpose of the third, non-load current carrying wire is to provide a path to ensure that the overcurrent protection will trip in the event of a line-to-case short circuit in a piece of equipment. This could either be the fuse or circuit breaker back at the main panel, or the fuse inside the equipment itself.

There is a secondary purpose — shock reduction: The electrical safety ground provides a common reference potential for all parts of the ac system. The conductive case of equipment is required to be connected to the bonded grounding system, which is also connected to earth ground at the service entrance, so someone who is connected to "earth" (for example, standing in bare feet on a conductive floor) that touches the case won't get shocked.

An effective safety ground system is necessary for every amateur station. If you have equipment at the base of the tower, generally, you need to provide a separate bonding conductor to connect the chassis and cases at the tower to the bonding system in the shack. **Figure 28.5A** shows an overall grounding system, emphasizing the requirement to bond all ground connections together, regardless of their purpose.

Equipment-to-equipment bonding can be done directly with wire (#6 to #14 AWG), strap (20 gauge), or through a bonding bus or single-point ground panel (SPGP). The equipment ground or "third-wire" connection in a residence's branch circuit must be made

### When to Use Strap, Wire, or Braid

The standard for grounding in the communication industry is solid strap or heavy wire. Both can be used indoors or outdoors. Flat-weave, tinned grounding braid can be used if the equipment is subject to vibration or needs to be moved around. Do not use any type of braid if it will be exposed to moisture or corrosive chemicals. Corrosion on the surface of the small wires used to make up the braid reduces its effectiveness by raising the surface resistance, where the RF currents flow. Poor contact between the individual wires can also result in noise and mixing products. Unless it is mechanically necessary, use solid strap or wire.

It is not recommended to reuse braid removed from coaxial cable. Once removed from its protective jacket, the braid wires immediately begin to loosen and oxidize or corrode. This reduces the braid's effectiveness at RF quite a bit, making it a poor choice for long-term grounding conductors.

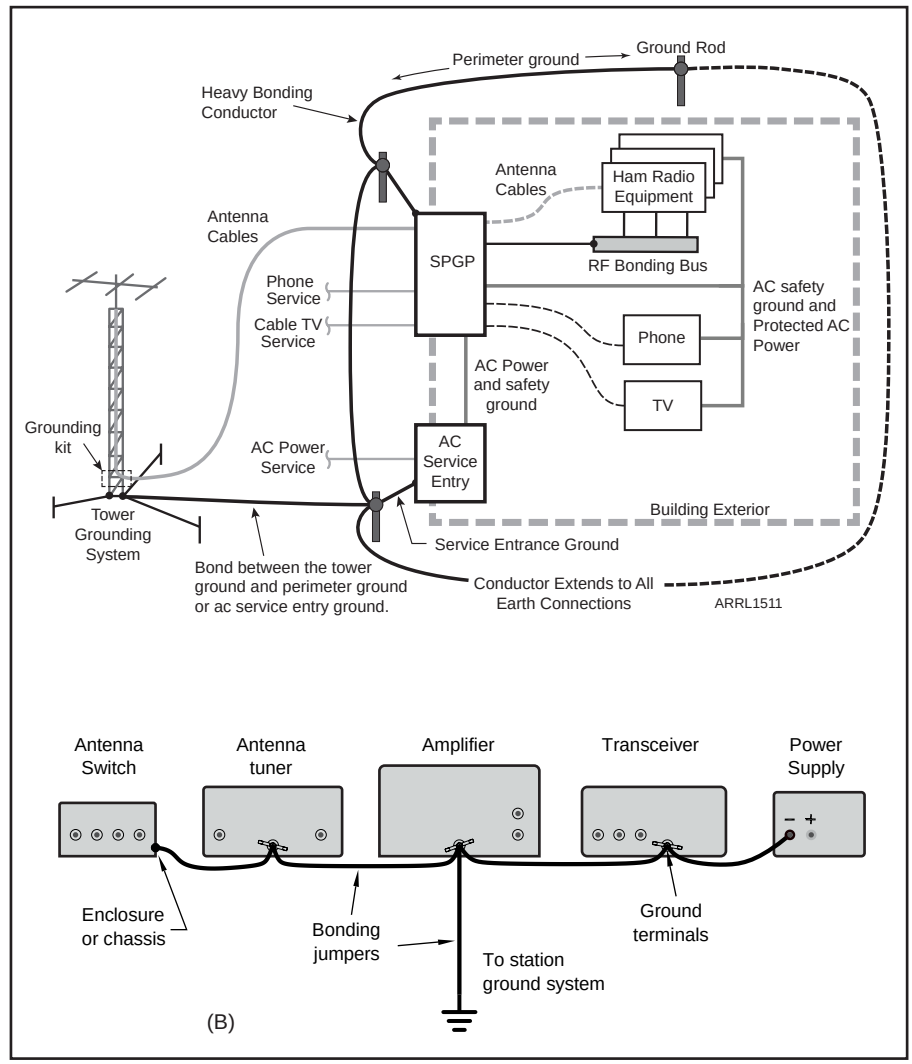

**Figure 28.5 — A grounding system that includes ac safety, lightning protection, and RF management. All ground electrodes must be bonded together and to the residence's ac service entry ground rod. If a protected ac branch circuit is included, the protector should be mounted on the SPGP (single-point ground panel). Direct equipment-to-equipment bonding (B) can be done with heavy wire or strap or to an RF bonding bus. See the chapter on Assembling a Station for more information on making these connections.**

with the same size wire as the hot and neutral conductors. Connections directly to a ground electrode, such as a ground rod, are made with heavy wire (#6 AWG minimum) or 20 gauge strap. Clamps and terminals should be rated or listed for grounding use, particularly for earth connections that are exposed to the weather or buried.

At ac power frequencies of 50 or 60 Hz, the wavelength is miles long so the electrical length of the connection is insignificant. Reactance created by the bonding conductor (about 1 nH per foot for a straight wire) is likewise negligible. The most important characteristics of the bonding connection is resistance and mechanical strength. Unfortunately, an effective bonding conductor at 60 Hz may present very high impedance at RF because of the inductance, or worse yet, wind up being an excellent antenna that picks up the signals radiated by your antenna.

## RF MANAGEMENT AND CHASSIS GROUND

"RF ground" is an obsolete term from days gone by when most operation was at low frequencies and a wire from the chassis or antenna tuner in the shack to a ground rod had low RF impedance. The RF voltage difference between the chassis and "Earth ground" was small. And even if there were small potential differences, the surrounding equipment of those days was relatively insensitive to them.

Today, we have a lot of circuits that are sensitive to interfering signals at millivolt levels, such as audio signals to and from sound cards. As a result, we can no longer ignore the RF voltage differences and shouldn't be using the equipment enclosures or shielding conductors as part of the RF circuit.

Instead, we design our stations to manage the RF picked up on cables, connecting wires, and enclosures so that it does not cause problems. The first step is to create a common reference potential, called the *ground plane* or *reference plane*. Equipment connected to the ground plane is maintained at a common potential. This minimizes RF current that would flow between pieces of equipment. (See the **RF Interference** and **Assembling a Station** chapters for more information.) The ground plane can be an actual sheet of metal or a low-inductance conductor to which all of the equipment can be connected, often called an *RF bonding bus*. The ground plane is then bonded to the station ground system.

It is sometimes suggested that RF grounds should be isolated from the ac safety and lightning protection ground system — that is not correct! All grounds, including safety, RF, lightning protection and commercial communications, must be bonded together in order to protect life and property. The electrical code requires that antenna grounds be bonded to the rest of the grounding system, although that connection can have an RF choke. Remember that the focus of the electrical code bonding requirement is safety in the event of a short to a power distribution line or other transient.

For decades, amateurs have been advised to bond all equipment cabinets to an RF ground located near the station. Given today's operating frequencies and equipment sensitivity, this practice is inadequate. Even a few meters of wire can have an impedance of hundreds of ohms (1 µH/meter = 88 Ω/meter at 14 MHz). So a better approach is to connect the chassis together in a well-organized fashion to ensure that the chassis-to-chassis connections minimize RF voltage differences as in Figure 28.5B. An RF bonding bus can be used, as well. (See the **RF Interference** and **Assembling a Station** chapters for more information.)

## LIGHTNING DISSIPATION GROUND

Lightning dissipation ground is concerned with conducting currents to the surrounding earth. There are distinct similarities between lightning dissipation ground systems and a good ground system for a vertical antenna. Lightning strokes produce electrical energy from a few kHz to more than 10 MHz so the length of the connection is important as well as its resistance. The difference is that an antenna ground plane may handle perhaps a few tens of amps, while the lightning ground needs to handle a peak current of tens of kiloamperes.

A typical lightning stroke is a pulse with a rise time of a few microseconds, a peak current of 20 to 30 kA, and a fall time of 50 µs. The average current is not all that high (a few hundred amps), so the conductor size needed to carry the current without melting is surprisingly small.

However, large conductors (usually specified as #6 AWG minimum by building codes) are used in lightning grounds for other reasons: to reduce inductance, to handle the mechanical forces from the magnetic fields, and for ruggedness to prevent inadvertent breakage. A large diameter wire, or even better, a wide flat strap, has lower inductance. The voltage along a wire is proportional to the change in current and its inductance:

$$|V| = L\frac{\Delta i}{\Delta t}$$

where

$\Delta i/\Delta t$ = rate of change in current, about 20kA/2µs for lightning, or $10^9$ A/s, and

L = the inductance of the wire.

Consider a connection box on a tower that contains some circuitry terminating a control cable from the shack, appropriately protected internally with overvoltage protection. If the connection from the box to ground is high inductance, the lightning transient will raise the box potential (relative to the wiring coming from the shack), possibly beyond the point where the transient suppression in the box can handle it. Lowering the inductance of the connection to ground reduces the potential.

The other reason for large conductors on lightning grounds is to withstand the very high mechanical forces from the high currents. This is also the reason behind the recommendation that lightning conductors be run directly, with minimal bends and large radii for bends that are needed, and certainly no loops. A wire carrying 20,000 A has a powerful magnetic field surrounding it, and if current is flowing in multiple wires that are close to each other, the forces pushing the wires together or apart can actually break the conductors or deform them permanently.

The force between two conductors carrying 20,000 A, spaced a centimeter apart, is 8000 Newtons/meter of length (over 500 pounds/foot). Such forces can easily break cable strands or rip up brackets and screws. This problem is aggravated if there are loops in the wire, since the interaction of the current and its magnetic field tends to make the loop get larger, to the point where the wire will actually fail from the tension stresses.

## EARTH GROUND

Earth ground usually takes one of several forms, all identified in the NEC and NFPA 780. The preferred earth ground, both as required in the NEC, and verified with years of testing in the field, is a *concrete encased grounding electrode* (CEGR), also known as a *Ufer ground*, after Herb Ufer, who invented it as a way to provide grounding for military installations in dry areas where ground rods are ineffective. The CEGR can take many forms, but the essential aspect is that a suitable conductor at least 20 feet long is encased in concrete which is buried in the ground. The conductor can be a copper wire (#8 AWG at least 20 feet long) or the reinforcing bars (rebar) in the concrete, often the foundation footing for the building. The connection to the rebar is either with a stub of the rebar protruding through the concrete's top surface or the copper wire extending through the concrete. There are other variations of the CEGR described in the NEC and in the electrical literature, but they're all functionally the same: a long conductor embedded in a big piece of concrete.

The electrode works because the concrete has a huge contact area with the surrounding soil, providing very low impedance and, what's also important, a low current density, so that localized heating doesn't occur. Con-

crete tends to absorb water, so it is also less susceptible to problems with the soil drying out around a traditional ground rod.

The techniques required for welding rebar and making the necessary connection to the CEGR are somewhat specialized. If you are not familiar with those skills, hire a professional to do the job correctly. Similarly, unless you have documented evidence that the necessary rebar connection or embedded wire are present in a concrete footing or slab, do not attempt to use it as a CEGR.

Ground rods are a traditional approach to making a suitable ground connection and are appropriate as supplemental grounds, say at the base of a tower, or as part of an overall grounding system. The best ground rods to use are those available from an electrical supply house. The code requires that at least 8 feet of the rod be in contact with the soil, so if the rod sticks out of the ground, it must be longer than 8 feet (10 feet is standard). The rod doesn't have to be vertical, and can be driven at an angle if there is a rock or hard layer, or even buried laying sideways in a suitable trench, although this is a compromise installation. Suitable rods are generally 10 feet long and made from steel with a heavy copper plating. (Stainless steel and galvanized rods are also available and may be required by soil conditions in your area. Check with a local electrician or electrical inspector.) Do not depend on shorter, thinly plated rods sold by some home electronics suppliers, as they can quickly rust and soon become worthless.

If multiple ground rods are installed, many references specify a minimum spacing of the rod's length. If the rods are not spaced by at least half the length of the rod, the effectiveness is compromised. IEEE Std 142 and IEEE Std 1100 (see the Reference listing) and other references have tables to give effective ground resistances for various configurations of multiple rods.

Once the ground rods are installed, they must be connected with either an exothermic weld (such as CadWeld) or with a listed pressure clamp. The exothermic weld is preferred, because it doesn't require annual inspection like a clamp does. Some installers use brazing to attach the wiring to the ground rods. Although this is not permitted for a primary ground, it is acceptable for secondary or redundant grounds. Soft solder (tin-lead, as used in plumbing or electrical work) should never be used for grounding conductors because it gets brittle with temperature cycling and can melt if a current surge (as from a lightning strike) heats the conductor. Soft solder is specifically prohibited in the code.

Building cold water supply systems were used as station grounds in years past, but this is no longer recommended or even permitted in some jurisdictions, because of increased used of plastic plumbing both inside and outside houses and concerns about stray currents causing pipe corrosion.. If you do use the cold water line, perhaps because it is an existing grounding electrode, it must be bonded to the electrical system ground, typically at the service entrance panel.

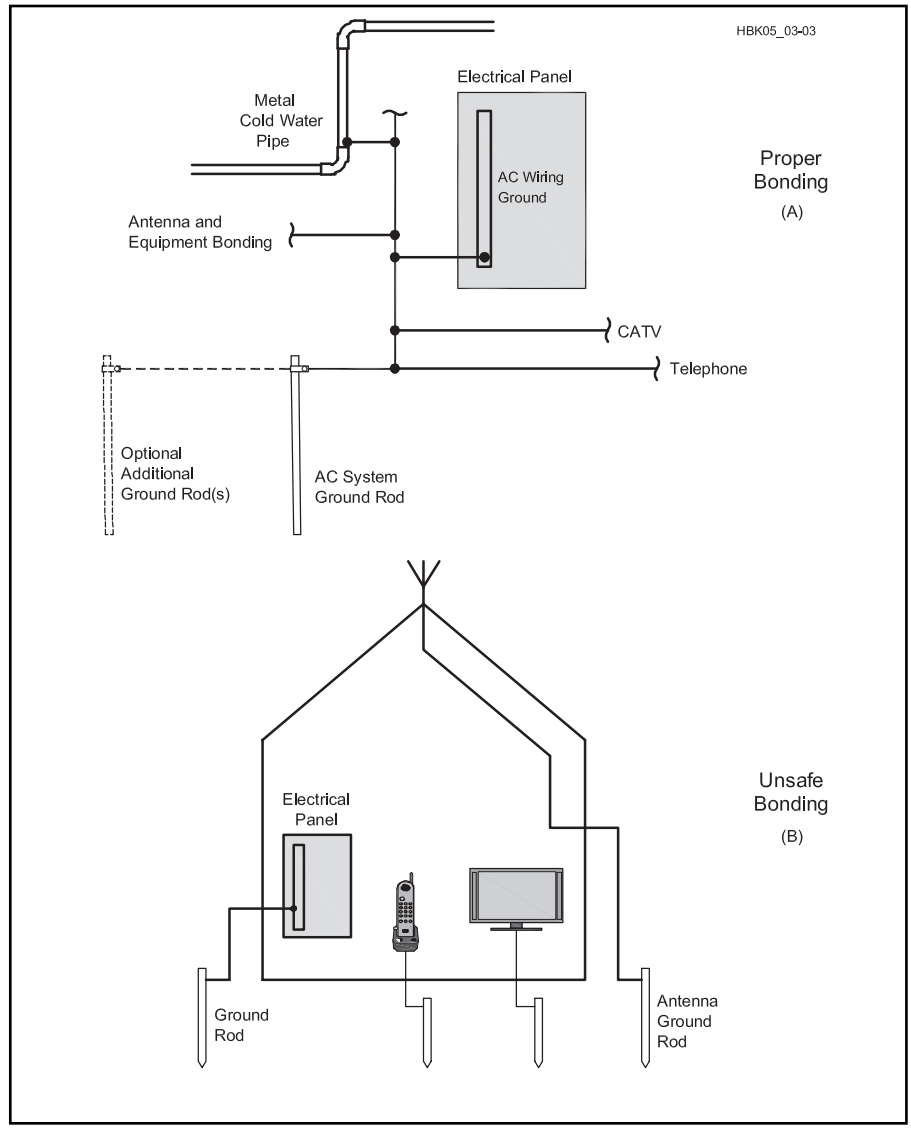

**Figure 28.6 — At A, proper bonding of all grounds to electrical service panel. The installation shown at B is unsafe — the separate grounds are not bonded. This could result in a serious accident or electrical fire.**

## 28.1.9 Ground Conductors

Building codes and wiring standards are quite specific as to the types of conductors that can be used for bonding the various parts of the system together. Grounding conductors may be made from copper, aluminum, copper-clad steel, bronze or similar corrosion-resistant materials. Note that the sizes of the conductors required are based largely on mechanical strength considerations (to insure that the wire isn't broken accidentally) rather than electrical resistance. Insulation is not required.

There is a "unified" grounding electrode requirement — it is necessary to bond *all* grounds to the electric service entrance ground. All utilities, antennas and any separate grounding rods used must be bonded together. **Figure 28.6** shows correct (A) and incorrect (B) ways to bond ground rods. **Figure 28.7** demonstrates the importance of correctly bonding ground rods. (Note: The NEC requirements do not address effective RF bonding. See the **RF Interference** and **Assembling a Station** chapters of this book for information about RF practices. Keep in mind that RFI is

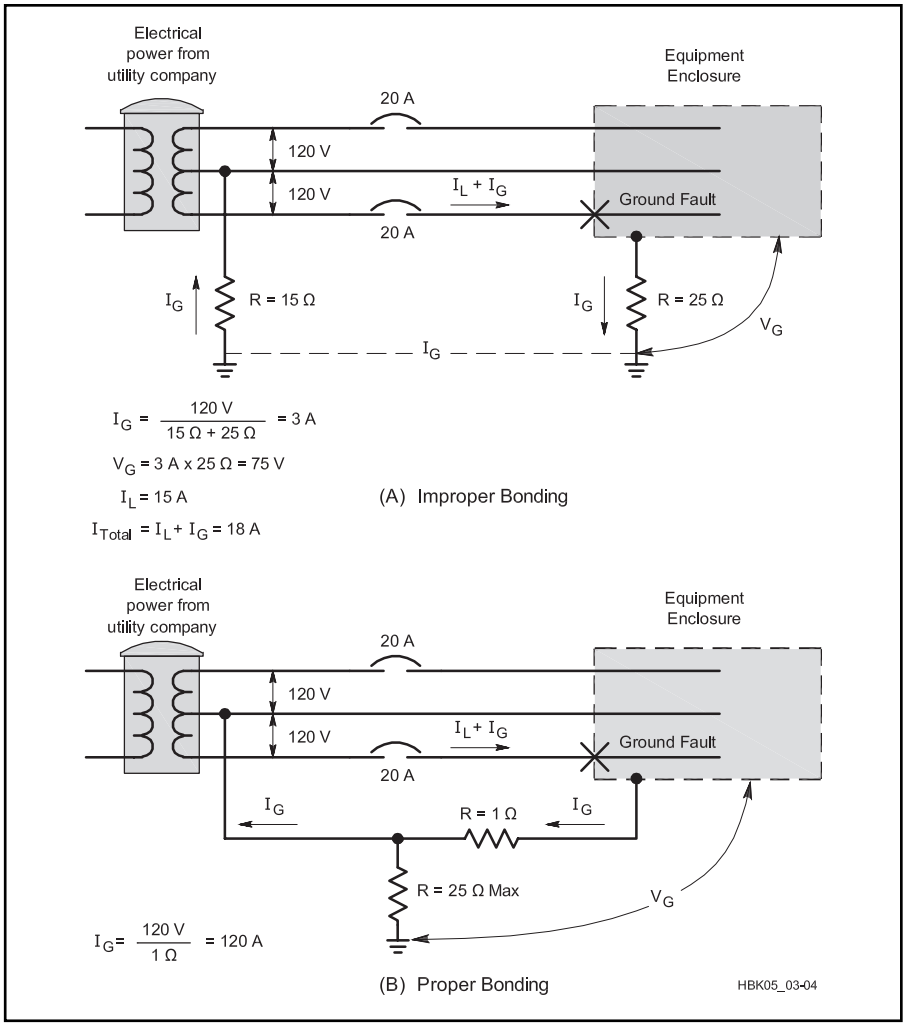

**Figure 28.7 — These drawings show the importance of properly bonded ground rods. In the system shown in A, the 20-A breaker will not trip. In the system in B, the 20-A circuit breaker trips instantly. There is an equipment internal short to ground — the ground rod is properly bonded back to the power system ground. Of course, the main protection should be in a circuit ground wire in the equipment power cord itself!**

## Coax Shields as a Grounding Conductor

The importance of significant current-carrying capability in a grounding conductor is determined by your local circumstances. If lightning is a problem or contact with power-carrying conductors due to wind or ice is a possibility, the ability of the coax shield to carry a lot of current is important and a separate grounding conductor is a good idea. In areas where hazards are reduced, a smaller conductor may suffice. Contact a licensed electrician if you aren't sure about what is prudent for your area.

not an acceptable reason to violate the NEC.) For additional information on good grounding practices, the *NEC Handbook* and IEEE "Emerald Book" (IEEE STD 1100-2005) are good references. Both are available through libraries. Home wiring guides are also available at home improvement stores.

Additionally, the NEC covers safety inside the station. All grounding conductors inside the building must be at least 4 inches away from conductors of any lighting or signaling circuit except when they are separated from other conductors by conduit or insulator. Other code requirements include enclosing transmitters in metal cabinets that are bonded to the grounding system. Of course, conductive handles and knobs must be grounded as well.

### 28.1.10 Antennas

Article 810 of the NEC includes several requirements for wire antennas and feed lines that you should keep in mind when designing your antenna system. The "protective grounding conductor" (main conductor running to the ground rod) must be as large as the antenna lead-in, but not smaller than #10 AWG. The grounding conductor (used to bond equipment chassis together) must be at least #14 AWG.

The single most important thing to consider for safety is to address the potential for contact between the antenna system and power lines. As the code says, "One of the leading causes of electric shock and electrocution, according to statistical reports, is the accidental contact of radio, television, and amateur radio transmitting and receiving antennas and equipment with light or power conductors." (See Article 810.13, Fine Print Note.) The requirements in the code for wire sizes, bonding requirements, and installation practices are mostly aimed at preventing tragedy, by avoiding the contact in the first place, and by mitigating the effects of a contact if it occurs.

Article 820 of the NEC applies to Cable TV installations, which almost always use coaxial cable, and which require wiring practices different from Article 810 (for instance, the coax shield can serve as the grounding conductor). Your inspector may look to Article 820 for guidance on a safe installation of coax, since there are many more satellite TV and cable TV installations than Amateur Radio. Ultimately, it is the inspector's call as to whether your installation is safe.

Article 830 applies to Network Powered Communication Systems, and as amateurs do things like install 802.11 wireless LAN equipment at the top of their tower, they'll have to pay attention to the requirements in this Article. The NEC requirements discussed in these sections are not adequate for lightning protection and high-voltage transient events. See the section "Lightning/Transient Protection" later in this chapter for more information.

#### ANTENNA CONDUCTORS

Transmitting antennas should use hard-drawn copper wire: #14 AWG for unsupported spans less than 150 feet, and #10 AWG for longer spans. Copper-clad steel, bronze or other high-strength conductors must be #14 AWG for spans less than 150 feet and #12 AWG for longer spans. Open-wire transmission line conductors must be at least as large as those specified for antennas. Stealth antennas made with light-gauge wire are not code-compliant.

#### LEAD-INS

There are several NEC requirements for antenna lead-in conductors (transmission

lines are lead-in conductors). For transmitting stations, their size must be equal to or greater than that of the antenna. Lead-ins attached to buildings must be firmly mounted at least 3 inches clear of the surface of the building on nonabsorbent insulators. Lead-in conductors must enter through rigid, noncombustible, nonabsorbent insulating tubes or bushings, through an opening provided for the purpose that provides a clearance of at least two inches; or through a drilled windowpane. All lead-in conductors to transmitting equipment must be arranged so that accidental contact is difficult. As with stealth antennas, installations with feed lines smaller than RG-58 are likely not code compliant depending on how your local inspector interprets the code.

### ANTENNA DISCHARGE UNITS (LIGHTNING ARRESTORS)

All antenna systems are required to have a means of draining static charges from the antenna system. A listed antenna discharge unit (lightning arrestor) must be installed on each lead-in conductor that is not protected by a permanently and effectively grounded metallic shield, unless the antenna itself is permanently and effectively grounded, such as for a shunt-fed vertical. Note that the usual transient protectors are *not* listed antenna discharge units.(The code exception for shielded lead-ins does *not* apply to coax, but to shields such as thin-wall conduit. Coaxial braid is neither "adequate" nor "effectively grounded" for lightning protection purposes.) An acceptable alternative to lightning arrestor installation is a switch (capable of withstanding many kilovolts) that connects the lead-in to ground when the transmitter is not in use. A garden-variety knife switch for household appliances is not adequately rated for this job.

### ANTENNA BONDING (GROUNDING) CONDUCTORS

In general the code requires that the conductors used to bond the antenna system to ground be at least as big as the antenna conductors, but also at least #10 AWG in size. Note that the antenna grounding conductor rules are different from those for the regular electrical safety bonding, or lightning dissipation grounds, or even for CATV or telephone system grounds.

### MOTORIZED CRANK-UP ANTENNA TOWERS

If you are using a motorized crank-up tower, the code has some requirements, particularly if there is a remote control. In general, there has to be a way to positively disconnect power to the motor that is within sight of the motorized device, so that someone working on it can be sure that it won't start moving unexpectedly. From a safety standpoint, as well, you should be able to see or monitor the antenna from the remote control point.

## Manufacturers of Lightning Protection Equipment

For current vendor contact information, use your favorite internet search tool.

- Alpha Delta Communications: Coax lightning arrestors, coax switches with surge protectors.
- The Wireman: copper wire up to #4 AWG, 2-inch flat copper strap, 8-ft copper clad ground rods and 1 × ¼-inch buss bar.
- ERICO International Corporation: CadWeld bonding system and lightning protection equipment.
- Harger Lightning & Grounding: lightning protection components.
- Industrial Communication Engineers, Ltd (ICE): Coax lightning arrestors.
- KF7P Metalwerks: Entrance panels, lightning arrestors, surge protectors, grounding and bonding hardware, and so on.
- PolyPhaser Corporation: Many lightning protection products for feed lines, towers, equipment, and so on.
- Zero Surge Inc: Power line surge protector.

## 28.1.11 Lightning/Transient Protection

Nearly everyone recognizes the need to protect themselves from lightning. From miles away, the sight and sound of lightning boldly illustrates its destructive potential. Many people don't realize that destructive transients from lightning and other events can reach electronic equipment from many sources, such as outside antennas, power, telephone and cable TV installations. Many hams don't realize that the standard protection scheme of several decades, a ground rod and simple "lightning arrestor," is *not* adequate.

Lightning and transient high-voltage protection follows a familiar communications scenario: identify the unwanted signal, isolate it and dissipate it. The difference here is that the unwanted signal is many megavolts at possibly 200,000 A. What can we do?

Effective lightning protection system design is a complex topic. There are a variety of system tradeoffs which must be made and which determine the type and amount of protection needed. A amateur station in a home is a very different proposition from an air traffic control tower which must be available 24 hours a day, 7 days a week. Hams can easily follow some general guidelines that will protect their stations against high-voltage events that are induced by nearby lightning strikes or that arrive via utility lines. Let's talk about where to find professionals first, and then consider construction guidelines.

### PROFESSIONAL HELP

Start with your local government. Find out what building codes apply in your area and have someone explain the regulations about antenna installation and safety. For more help, look in your telephone yellow pages for professional engineers, lightning protection suppliers and contractors.

Companies that sell lightning-protection products may offer considerable help to apply their products to specific installations. One such source is PolyPhaser Corporation. Look under "References" later in this chapter for a partial list of PolyPhaser's publications.

### CONSTRUCTION GUIDELINES

#### Bonding Conductors

Copper strip (or *flashing*) comes in a number of sizes. The *minimum* recommended grounding conductor for lightning protection is 1.5 inches wide and 0.051 inch thick or #6 AWG stranded wire. Do not use braided strap outside or in wet areas because the individual strands oxidize over time, greatly reducing the effectiveness of braid as an ac conductor. Bear in mind that copper strap has about the same inductance as a wire of the same length. While strap may be easier to install and provides a lower RF loss (if it's part of a vertical antenna grounding system, for instance), it doesn't provide significant improvement over round wire for power line frequencies (the NEC's concern) or lightning (where inductance dominates the effects).

Use bare copper for buried ground wires. (There are some exceptions; seek an expert's advice if your soil is corrosive.) Exposed runs above ground that are subject to physical damage may require additional protection (a conduit) to meet code requirements. Wire size depends on the application, but never use anything smaller than #6 AWG for bonding earth electrodes. The NEC specifies conductors using wire gauge, and doesn't describe the use of flashing. Local lightning-protection experts or building inspectors can recommend sizes for each application.

#### Tower and Antennas

Because a tower is usually the highest metal object on the property, it is the most likely strike target. Proper tower grounding is essential to lightning protection. The goal is to establish short multiple paths to the Earth so that the strike energy is divided and dissipated.

Connect each tower leg and each fan of metal guy wires to a separate ground rod.

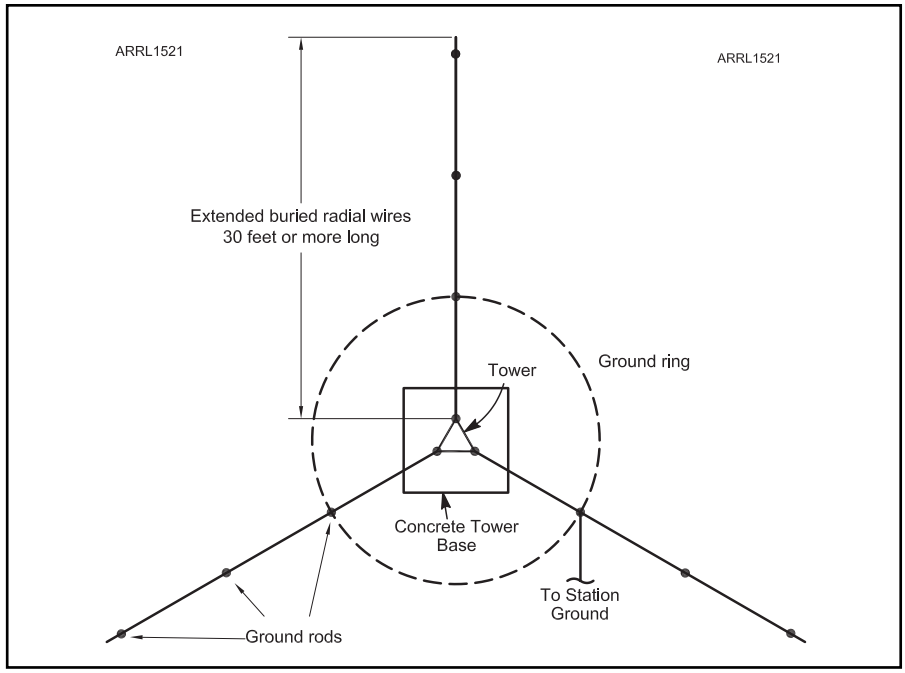

**Figure 28.8 — Schematic of a properly grounded tower. A bonding conductor connects each tower leg to a ground rod and a buried (1 foot deep) bare, tinned copper ring (dashed line), which is also connected to the station ground and then to the ac safety ground. Make the ring diameter large enough that ground rods aligned with the tower legs will be approximately 6 feet apart. Buried radial wires extending beyond the ring are a common commercial practice and provide extra protection but are optional. All connectors should be compatible with the tower and conductor materials to prevent corrosion. See text for conductor sizes and details of lightning and voltage transient protection.**

## Voltage Rise On Wires With Fast Transients

A rule of thumb is that a single wire has an inductance of about 1 µH per meter of length. The voltage across an inductor $V = L\,\Delta i/\Delta t$. ($\Delta i/\Delta t$ is the change in current per unit of time.) A lightning stroke has a rise time of about 1-2 µs, so the current might go from zero to 10 kA in a microsecond or two, a $\Delta i/\Delta t$ of over 1 kA/µs ($10^9$ A/s). An inductance as low as 1 µH would create a voltage of 1000 volts from this current transient.

Space the rods at least 6 feet apart. Bond the leg ground rods together with #6 AWG or larger copper bonding conductor (form a ring around the tower base, see **Figure 28.8**). Connect a continuous bonding conductor between the tower ring ground and the entrance panel. Make all connections with fittings approved for grounding applications. *Do not use solder for these connections.* Solder will be destroyed in the heat of a lightning strike.

Because galvanized steel (which has a zinc coating) reacts with copper when combined with moisture, use stainless steel hardware between the galvanized metal and the copper grounding materials. Rohn and other manufacturers now offer ground clamps designing for connecting galvanized tower legs to copper ground conductors.

To prevent strike energy from entering a shack via the feed line, ground the feed line *outside* the home. Ground the coax shield *to the tower* at the antenna and the base to keep the tower and line at the same potential. Several companies offer grounding blocks that make this job easy.

All grounding media at the home must be bonded together. This includes lightning-protection conductors, electrical service, telephone, antenna system grounds and underground metal pipes. Any ground rods used for lightning protection or entrance-panel grounding should be spaced at least 6 feet from each other and the electrical service or other utility grounds and then bonded to the ac system ground as required by the NEC.

### A Single-Point Ground Panel (SPGP)

The basic concept with transient protection is to make sure that all the radio and other equipment is tied together and "moves together" in the presence of a transient voltage. It's not so important that the shack be at "ground" potential, but, rather, that everything is at the *same* potential. For fast rise-time transients such as the individual strokes that make up a lightning strike, even a short wire has enough inductance that the voltage drop along the wire is significant, so whether you are on the ground floor, or the 10th floor of a building, your shack is "far" from Earth potential.

The easiest way to ensure that everything is at the same potential is to tie all the signal ground connections to a common reference. In large facilities, this reference would be provided by a grid of large diameter cables under the floor, or by wide copper bars, or even a solid metal floor. A more practical approach for smaller facilities such as a ham shack is to have a *single-point ground panel* (SPGP). The SPGP may be a separate metal panel or it can be enclosed in an electrical box. See the articles by Block in the References section for a complete discussion of the SPGP. The articles are available online through the ARRL's Radio Technology Topics website (**www.arrl.org/radio-technology-topics**) under Safety and in the ARRL book *Grounding and Bonding for the Radio Amateur*.

The SPGP should be mounted outside the building. The easiest way to do this is to install a large metal enclosure or a metal panel as a bulkhead and grounding block. The panel should be connected to the lightning dissipation ground with a short wide conductor (for minimum impedance), and, like all grounds, bonded to the electrical system's ground. Mount all protective devices, switches, and relay disconnects on the outside facing wall. The enclosure or panel should be installed in a way that if lightning currents cause a component to fail, the molten metal and flaming debris do not start a fire.

Every conductor that enters the structure, including antenna system control lines, telephone, and CATV cables, should have its own surge suppressor on an entrance panel. Suppressors are available from a number of manufacturers, including Industrial Communication Engineers (ICE) and PolyPhaser, as well as the usual electrical equipment suppliers such as Square-D.

We want to control the flow of the energy in a strike and eliminate any possible paths for surges to enter the building. Route feed lines, rotator control cables, and so on at least six feet away from other nearby grounded metal objects. Keep incoming, unprotected cables well away from cables on the protected side of any lightning arrestors, as well.

### Lightning Arrestors

Feed line lightning arrestors are available for both coax cable and balanced line. Most of the balanced line arrestors use a simple spark gap arrangement, but a balanced line

*impulse* suppressor is available from ICE.

DC blocking arrestors for coaxial cable have a fixed frequency range. They present a high-impedance to lightning (less than 1 MHz) while offering a low impedance to RF.

DC continuity arrestors (gas tubes and spark gaps) can be used over a wider frequency range than those that block dc. Where the coax carries supply voltages to remote devices (such as a mast-mounted preamp or remote coax switch), dc-continuous arrestors *must* be used.

## 28.1.12 Other Hazards in the Station

### UPS AND ALTERNATE ENERGY SOURCES

Many hams have alternate energy sources for their equipment, or an uninterruptible power supply (UPS), so that they can keep operating during a utility power outage. This brings some additional safety concerns, because it means that the "turning off the breaker" approach to make sure that power is disconnected might not work.

In commercial installations, fire regulations or electrical codes often require that the emergency power off (EPO) system (the big red button next to the door) also disconnect the batteries of the UPS system, or at least, disable the ac output. This is so that firefighters who may be chopping holes with conductive tools or spraying conductive water don't face the risk of electrocution. (According to NEC, Articles 645-10 and 645-11, UPSs above 750 VA installed within information technology rooms must be provided with a means to disconnect power to all UPS supply and output circuits. This disconnecting means shall also disconnect the battery from its load. The code further requires that the control for these disconnecting means shall be grouped and identified and shall be readily accessible at the principal exit doors.)

A similar problem exists with solar panel installations. Just because the breaker is turned off doesn't mean that dangerous voltages don't exist on the solar panel. As long as light is falling on them, there is voltage present. With no load, even a relatively dim light falling on part of the panels might present a shock or equipment damage hazard. Modern grid-tie solar systems with no batteries often have the panels wired in series, so several hundred volts is not unusual.

Recent revisions of the NEC have addressed many of the aspects of photovoltaic (PV) installations that present problems with disconnects, bonding, and grounding. Consulting your local authorities is always wise, and there are several organizations such as the Southwest Technology Development Institute at New Mexico State University that have prepared useful information (see the references at the end of this section). In general, PV systems at 12 or 24 V aren't covered by the NEC.

### ENERGIZED CIRCUITS

Working with energized circuits can be very hazardous since, without measuring devices, we can't tell which circuits are live. The first thing we should ask ourselves when faced with troubleshooting, aligning or other "live" procedures is, "Is there a way to reduce the hazard of electrical shock?" Here are some ways of doing just that.

1) If at all possible, troubleshoot with an ohmmeter. With a reliable schematic diagram and careful consideration of how various circuit conditions may reflect resistance readings, it will often be unnecessary to do live testing.

2) Keep a fair distance from energized circuits. What is considered "good practice" in terms of distance? The NEC specifies minimum working space around electric equipment depending on the voltage level. The principle here is that a person doing live work needs adequate space so they are not forced to be dangerously close to energized equipment.

3) If you need to measure the voltage of a circuit, install the voltmeter with the power safely off, back up, and only then energize

## Fire Extinguishers in the Amateur Station

Every amateur station should have a fire extinguisher at hand. Three classes of fire extinguishers are appropriate for amateur stations:

- Class A: Combustible solid materials such as wood or paper
- Class B: Combustible liquid or gases
- Class C: Energized electrical fire

A fixed or portable station should have "ABC" class extinguishers. Mobile stations are most likely to experience class B and C fires. Liquid water extinguishers or hoses should never be used on an electrical fire because most water is a conductor of electricity and creates an electrical shock hazard. For more information on fire extinguishers, see the chapter "Assembling a Station."

## Electrical Shock Hazards and Effects

**What happens when someone receives an electrical shock?**

Electrocutions (fatal electric shocks) usually are caused by the heart ceasing to beat in its normal rhythm. This condition, called ventricular fibrillation, causes the heart muscles to quiver and stop working in a coordinated pattern, in turn preventing the heart from pumping blood.

The current flow that results in ventricular fibrillation varies between individuals but may be in the range of 100 mA to 500 mA. At higher current levels the heart may have less tendency to fibrillate but serious damage would be expected. Studies have shown 60-Hz alternating current to be more hazardous than dc currents. Emphasis is placed on application of cardiopulmonary resuscitation (CPR), as this technique can provide mechanical flow of some blood until paramedics can "restart" the heart's normal beating pattern. Defibrillators actually apply a carefully controlled waveform to "shock" the heart back into a normal heartbeat. It doesn't always work but it's the best procedure available.

**What are the most important factors associated with severe shocks?**

You may have heard that the current that flows through the body is the most important factor, and this is generally true. The path that current takes through the body affects the outcome to a large degree. While simple application of Ohm's Law tells us that the higher the voltage applied with a fixed resistance, the greater the current that will flow. Most electrical shocks involve skin contact. Skin, with its layer of dead cells and often fatty tissues, is a fair insulator. Nonetheless, as voltage increases the skin will reach a point where it breaks down. Then the lowered resistance of deeper tissues allows a greater current to flow. This is why electrical codes refer to the term "high voltage" as a voltage above 600 V.

**How little voltage can be lethal?**

This depends entirely on the resistance of the two contact points in the circuit, the internal resistance of the body, and the path the current travels through the body. Historically, reports of fatal shocks suggest that as little as 24 V *could* be fatal under extremely adverse conditions. To add some perspective, one standard used to prevent serious electrical shock in hospital operating rooms limits leakage flow from electronic instruments to only 50 µA due to the use of electrical devices and related conductors inside the patient's body.

the circuit. Remove the power before disconnecting the meter.

4) If you are building equipment that has hinged or easily removable covers that could expose someone to an energized circuit, install interlock switches that safely remove power in the event that the enclosure is opened with the power still on. Interlock switches are generally not used if tools are required to open the enclosure.

5) Never assume that a circuit is at zero potential even if the power is switched off and the power cable disconnected. Capacitors can retain a charge for a considerable period of time and may even partially recharge after being discharged. Bleeder resistors should be installed, but don't assume they have discharged the voltage. Instead, after power is removed and disconnected use a "shorting stick" to ground all exposed conductors and terminals to ensure that voltage is not present. If you will be working with charged capacitors that store more than a few joules of energy, you should consider using a "discharging stick" with a high wattage, low value resistor in series to ground that limits the discharge current to around 5-10 A. A dead short across a large charged capacitor can damage the capacitor because of internal thermal and magnetic stress. Avoid using screwdrivers, as this brings the holder too close to the circuit and could ruin the screwdriver's blade. For maximum protection against accidentally energizing equipment, install a shorting lead between high-voltage circuits and ground while you are working on the equipment.

6) Shorting a series string of capacitors does not ensure that the capacitors are discharged. Consider two 400 µF capacitors in series, one charged to +300 V and the other to –300 V with the midpoint at ground. The net voltage across the series string is zero, yet each has significant (and lethal) energy stored in it. The proper practice is to discharge each capacitor in turn, putting a shorting jumper on it after discharge, and then moving to the next one.

7) If you must hold a probe to take a measurement, always keep one hand in your pocket. As mentioned in the sidebar on high-voltage hazards, the worst path current could take through your body is from hand to hand since the flow would pass through the chest cavity.

8) Make sure someone is in the room with you and that they know how to remove the power safely. If they grab you with the power still on they will be shocked as well.

9) Test equipment probes and their leads must be in very good condition and rated for the conditions they will encounter.

10) Be wary of the hazards of "floating" (ungrounded) test equipment. A number of options are available to avoid this hazard.

11) Ground-fault circuit interrupters can offer additional protection for stray currents that flow through the ground on 120-V circuits. Know their limitations. They cannot offer protection for the plate supply voltages in linear amplifiers, for example.

12) Older radio equipment containing ac/dc power supplies have their own hazards. If you are working on these live, use an isolation transformer, as the chassis may be connected directly to the hot or neutral power conductor.

13) Be aware of electrolytic capacitors that might fail if used outside their intended applications.

14) Replace fuses only with those having proper ratings. The rating is not just the current, but also takes into account the speed with which it opens, and whether it is rated for dc or ac. DC fuses are typically rated at lower voltages than those for ac, because the current in ac circuits goes through zero once every half cycle, giving an arc time to quench. Switches and fuses rated for 120 V ac duty are typically not appropriate for high-current dc applications (such as a main battery or solar panel disconnect).

# 28.2 Antenna and Tower Safety

The topic of antenna and tower safety is by no means an academic pursuit. In 2019 and 2020 alone, there were six recorded fatalities related to amateur radio tower work and serious injuries in other instances. The causes of these tragic incidents were all identifiable in advance and avoidable. With careful attention and care, no ham needs to lose his or her life, or sustain serious injury in the course of working on an antenna system.

Whether the chosen antenna support is as simple as a tree, or as sophisticated as a tall, purpose-built tower, every antenna project can present risks to life and limb. Some of the hazards that may be encountered include:

- Electrical hazards
- Structural failures
- Hazards associated with lifting and lowering equipment
- Falls from substantial height
- Challenging weather
- Falling objects
- Equipment failure

In the initial section, we introduce some important ways of thinking and working that are likely to make for a safe day of antenna work. This material here presents a good overview of safety issues and practices associated with antennas and supporting structures. The remainder of the sections focus primarily on safety issues encountered during tower construction and maintenance, although the techniques may also apply to other types of antenna supports.

## 28.2.1 Planning for Safety

Safety isn't something you can just *set-and-forget*. It's not just *buy-and-be-done*. It's a way of thinking; it's pervasive; it should be ingrained in everything you do. Done right, safety practices result in long-term benefits.

Every antenna project has a lifetime that comprises several important phases. Those phases include *Planning*, *Construction*, *Maintenance*, and *Removal*. Let's take a look at each of these phases and the safety practices that can be incorporated into each one.

### THE PLANNING PHASE

Every antenna project starts with some sort of *Planning*. Whether it's a simple wire antenna or a much bigger installation involving a tower and rotatable antennas, you'll need to make a range of important decisions before you begin to build.

*Design* is perhaps the most critical part of the planning phase. In antenna system design, you will consider questions about the location of the antenna system; the size, weight and strength of the pieces and parts that will be employed; and the strength of all supporting components. Factors such as climate and weather, desired lifetime, maintenance requirements, budgets, and local regulations will all factor into your design. Getting the design right is particularly important because it sets the stage for what will happen throughout the full lifetime of the system. A good design is likely to result in a system that will be effective, reliable and safe over the course of its entire lifetime.

*Conservativism* is the watchword for a safe project. Maximum safety can best be ensured by creating the path forward from a conservative perspective. Conservative goals and specifications will not only increase safety margins for the project; they reduce the effort and cost associated with the later phases of construction, maintenance, and removal.

### THE CONSTRUCTION PHASE

*Construction* describes the time during which the antenna or antenna support structure is erected, usually one or more days of concentrated effort by a team of hams. Construction is one of the two phases in the life of an antenna or tower during which risk of injury is highest. Some of those involved might have experience, while others are new to the process of antenna and tower construction. Fueled by excitement and anticipation of the moment when the project will be ready to test, the build team is often motivated to get the job done quickly. With pressure to complete any job in the least possible amount of time comes the temptation to cut corners or distractions from safe procedures. The best planning is easily compromised when team members decide to skip steps, work with insufficient skills or tools, or omit critical procedures. This is a period when everyone must be vigilant about keeping safe practices front-and-center.

### THE MAINTENANCE PHASE

Once the new antenna or tower has been fully installed and tested, its service life begins. Every owner/operator of an antenna system hopes for a long lifetime of trouble-free operation. But wear-and-tear is a fact of life for all mechanical and electrical devices. Some forms of degradation are predictable, such as loosening of nuts and bolts, corrosion, and wear on ropes or cables exposed to friction. These can and should be addressed with *preventative maintenance* (PM) steps. Annual checkups of hardware are a must. Replace antenna support ropes before they fail, perhaps bi-annually. PM will prevent much bigger problems and help avoid the need for much bigger and riskier repair projects.

### THE REMOVAL PHASE

The remaining risky phase in the life of an antenna project — particularly with respect to a tower —— is removal. A variety of risks present themselves during the take-down of an existing tower. Let's consider two of the most common safety risks related to removal of a tower.

#### Unknown Construction Materials and Methods

It is not uncommon for hams to assist in removal of a tower or other antenna structure when a ham is moving or is otherwise no longer able to use it. After asking the first few questions, it is very common to find that the original construction details were not documented. Is there concrete in the base and anchors of a guyed tower? How much? How is the roof tower attached to the roof? What material was used for the mast? Can it be identified simply by visual inspection? When the answers to these questions are unknown, workers face significant risks. If there isn't sufficient information to make a safety determination, there is only one correct plan of action — call in the professionals.

#### Old Installations

When an installation has been in place for many years, the risks increase. Corrosion is almost certain to have invaded the hardware. Frequently, the corrosion is invisible; even a trained professional may have difficulty detecting it. The opportunity to take on a removal project in exchange for the salvage value of a tower and antennas is a temptation that should be avoided. If you are not highly trained and experienced in working with tower and antenna installations, the right course of action is to call in the professionals.

## 28.2.2 Antenna Supports and Structures

### TREES

The original antenna supports were trees: if you've got them, use them. They're free and unregulated, so it couldn't be easier. Single-trunked varieties such as fir and pine are easier to use than the multi-trunked varieties. Multi-trunked trees are not impossible to use but they require more work. For dipoles or other types of wire antennas, plan for the tree to support an end of the wire; trying to install a center-supported inverted V or similar configuration is almost impossible due to all of the intervening branches.

Even when working with trees, it's important to be aware of the potential for safety hazards. There are two primary safety risks associated with using trees as antenna supports:

#### Proximity to Power Lines

Antennas are metallic and must be kept a substantial distance from power lines. Any wire or tubing coming in accidental contact with a power line is a lethal hazard. Even antennas protected by non-conductive sleeves must be kept from contacting power lines. When you choose trees as your antenna supports, inspect the tree carefully. It is important to avoid using trees that are in close proximity to any power lines that may be difficult to see in or near the tree. Without expert knowledge, you should assume that any wires on utility poles and any wires entering your home at a service entry point are dangerous and must be avoided.

#### Climbing

In general, safely climbing a tree to install an antenna requires special equipment and training in techniques that protect both the tree and the climber. Professional arborists and tree services have all the necessary experience and equipment. Professional tree climbers are often willing to help out for a small fee.

There are quite a few options to support your antenna high in a tree without climbing. Rope saws, pole trimmers, ropes, pulleys, and other tools can establish a strong and secure support point for your antenna.

If you can safely gain access to the tree at the desired height, an effective method is to install a screw-eye with a pulley into the trunk or a strong branch, then trim enough limbs to create a "window" for the antenna through the branches. Finally, attach a rope halyard to the antenna insulator. Here's a useful tip: Make the *halyard* a continuous loop as shown in **Figure 28.9**. Since it's almost always the antenna wire that breaks, a continuous halyard makes it easy to reattach the wire and insulator. With just a single halyard, if the

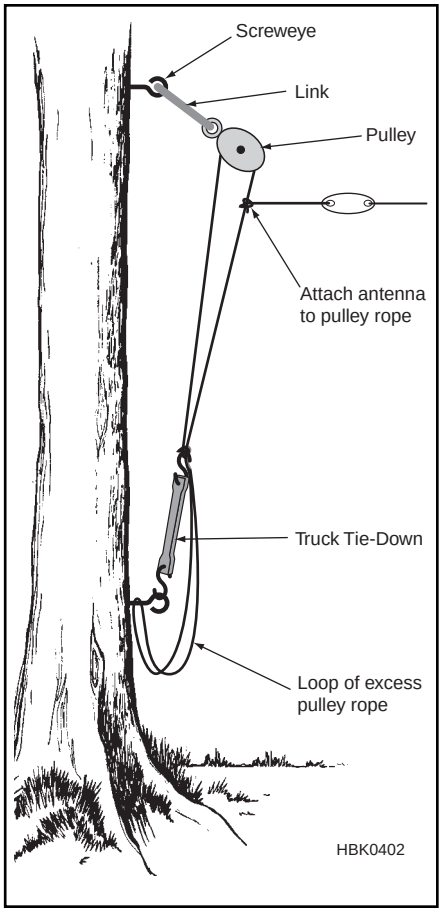

**Fig 28.9 — Loop and halyard method of supporting wire antennas in trees. Should the antenna break, the continuous loop of rope allows antenna repair or replacement without climbing the tree.**

antenna breaks, the tree will have to be climbed to reach the pulley, then reinstall and attach the line.

Another popular option to get your wires high in the trees is by using some sort of launcher. Using a bow-and-arrow is a traditional method of shooting a fishing line over a tree to pull up a bigger line. Some use a slingshot or a fishing rod with a well-chosen weight to get the initial line over a high branch. There are commercial compressed-air launchers or "spud guns" that can reach heights of more than 200 feet! One of the secrets to success in all of these techniques is to start with a light fishing line holding a weight large enough to pull the line back to the ground through the tree. Then use the light line to pull a mid-weight line over the branch, and finally pull the heavy-duty rope into place. The initial weight should be brightly colored so you can find it either on the ground or in the tree.

### MASTS AND POLES

Ground-mounted masts and poles come in a wide variety of sizes and strengths. Telescoping fiberglass poles are popular supports for wire antennas, particularly for portable and temporary use. Light-duty TV antenna push-up masts can support small beam antennas. AB-155 military surplus masts use stackable sections of fiberglass and aluminum tubing supported by guys and tripods. Another military-style mast, the AB-577 is an all-aluminum crank-up mask often called a "rocket launcher" that can support a medium-sized HF beam.

All types of masts present challenges; don't overload them. None of the choices listed here can be climbed, so antennas or mounting gear must be attached at ground level before the mast is raised. Masts with antennas installed can bend or break when being "walked up" to vertical from a horizontal position. Stackable sections require sturdy supports to hold the mast vertical as the mast is lifted to add more sections from the bottom. The mast manufacturer will provide directions and safe loading information. These instructions must be followed to avoid damaging the mast or causing injuries. It is also wise to have a supervisor or observer monitor progress and watch out for unsafe situations as the mast is being erected.

A mast's flexibility makes the side guys especially important since they keep it from bending sideways under load. Masts require extra care during installation to be sure they are kept straight. Once a curve develops, a collapse can occur very quickly. If a team is required to manage guys as the mast is raised, a practice session should be arranged so that everyone knows the procedure and coordinating instructions are followed.

Steel push-up masts are heavy, especially when raising the final sections that are carrying the full weight of the extended mast. A slipping section can seriously injure fingers and hands. Push-up masts can be walked up, but only with light antennas attached (the top section is likely to bend if loaded when it is not vertical).

Wooden utility poles, new or used, are very sturdy but are not cheap, require special installation with a pole-setting truck, and there is no commercial antenna mounting hardware available for them. That makes them a poor choice for most installations. Do not use existing utility poles as antenna supports if they support utility lines of any type.

### TOWERS

Towers require a significant effort to design and install a safe, effective system but are the only viable choice for large, rotatable antennas and arrays. Along with being able to support the weight and torque of larger antennas and accessory equipment, the options offered by commercial tower manufacturers allow each individual tower installation to be purpose-built to suit the needs of the station owner. A wide variety of requirements can be satisfied with selection of the right tower type and proper construction. There are many safety issues involved that require careful planning and preparation. These are discussed in the following sections.

Using towers for portable and temporary stations has its own set of safety challenges. It is common on Field Day, for example, to erect towers of 20 to 40 feet to support a small HF beam. The June 2013 *QST* article "Field Day Towers — Doing It Right" by Daso and Silver presents information about and guidelines for temporary tower installation.

## 28.2.3 Build It by the Book

Every aspiring antenna system builder/owner needs to understand and follow two types of information that constrain or guide construction and installation:

#### Regulations

Most antenna support structures fall under local building regulations as well as neighborhood restrictions. Many housing developments have Homeowner's Associations (HOAs) as well as Covenants, Conditions and Restrictions (CC&Rs) that may have a direct bearing on whether a tower or similar structure can be erected at all, and if allowed, how it must be constructed for safety and other concerns. This is a broad topic with many facets. Detailed background on these topics is provided in *Antenna Zoning for the Radio Amateur* by Fred Hopengarten, K1VR, an attorney with extensive experience in towers and zoning. You may also want to contact one of the ARRL Field Organization's Volunteer Counsels.

Even without neighborhood restrictions, a building permit is likely to be required. With the proliferation of cellular and other commercial wireless devices and their attendant RF sites, many local governments now require that all antenna support structures meet local building codes. Again, K1VR's book is extremely helpful in sorting all this out. Building permit applications may also require Professional Engineer (PE) calculations and stamp (certification). The ARRL Field Organization's Volunteer Consulting Engineer program may be useful with the engineering side of your project.

It is important to understand that building regulations are the cumulative results of decades of experience — and that compliance with them will result in a structure that is both stronger and safer for you and your neighbors. Working closely with the local building department is often a source of useful knowledge and tips for a better installation. It also gives you permits and signoffs that can provide a level of liability protection in the event of a future incident.

### Manufacturers' Guidelines

As you explore the various options in the world of commercial antenna supports, you will find that every manufacturer provides clear instructions on how their products should be installed and specifications of the minimum performance that should be expected when installed per the manufacturer's instructions. This information is developed by design engineers and is usually signed off by a registered Professional Engineer to certify that the design is in alignment with standard building codes, such as the International Building Code (IBC). The IBC is the base building code used by most jurisdictions in the United States. (See the sidebar on the NEC in the Electrical Safety section earlier in this chapter for more information on building codes.)

Former tower climber Steve Morris, K7LXC says it well in what is affectionately known in the amateur radio world as the K7LXC Prime Directive — "DO what the manufacturer says." Follow the corollary as well — "DON'T do what the manufacturer doesn't say to do." Professional engineers have analyzed and calculated the proper specifications and conditions for tower structures and their environment. Taking shortcuts or making different decisions will result in a less reliable installation. It is also important to note here that every installation is unique. Your analysis may reveal that even the manufacturer's recommendations are not conservative enough for your particular situation and needs.

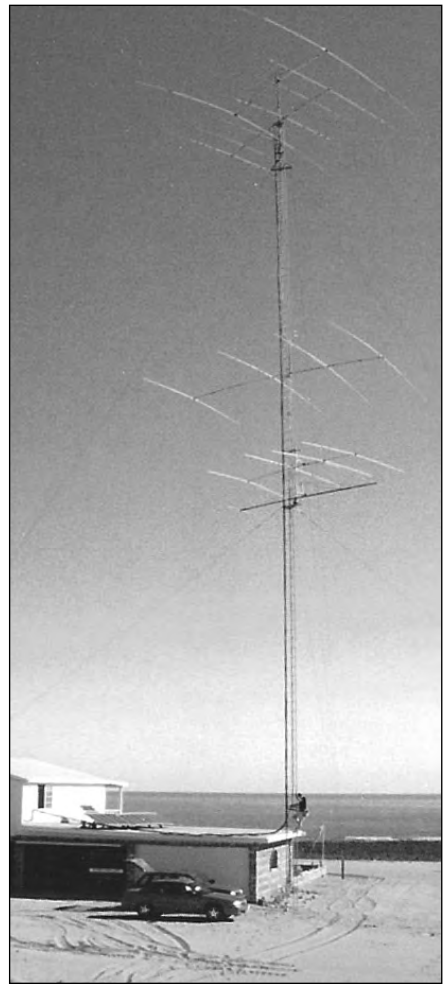

**Figure 28.10 — A guyed tower with a good-sized load of antennas at XE2DV-W7ZR in Baja California, is shown at the left. At the right, the Trylon Titan self-supporting tower of W7WVF and N7YYG in Bandon, Oregon. [Steve Morris, K7LXC, photos]**

## DESIGN CONSIDERATIONS

Safety starts with design. Two critically important design parameters to consider when planning a tower installation are the maximum local *wind speed* and the proposed antenna *wind load*. Tower capacities are generally specified in square feet of antenna load. Check with your local building department to find out what the maximum wind speed is for your area. Another source is a list of maximum wind speeds for all counties in the US from the TIA-222, *Structural Standard for Antenna Supporting Structures and Antennas*. (TIA-222-H is the latest revision as of early 2021.) A list of wind speeds by county based on TIA-222-G is available online at **wirelessestimator.com/content/standards**.

Antenna wind load specifications are provided by the antenna manufacturer. It's important to note that when installing a mast with several antennas, the total effective wind load on the tower is not a simple sum of the wind loads of the various antennas. The true load of each antenna will increase with its height above the top of the tower. The forces on the top of the tower by A 10 sq. ft. antenna mounted 10 feet above the tower on a long mast will subject the tower to much greater forces than the same antenna mounted right at the top plate of the tower. A proper calculation of wind load should be done by a trained structural engineer. (A procedure for calculating load and mast strength is provided in the *ARRL Antenna Book*.)

Towers come in the guyed and self-supporting varieties shown in **Figure 28.10**. Each has its own safety issues. Guyed towers require a bigger footprint because the guys have to be anchored away from the tower — typically 80% of the tower height. Self-supporting towers need bigger bases to counteract the overturning moment and are more expensive than a guyed tower because there is more steel in them (the cost of a tower is largely determined by the cost of the steel).

The most popular guyed towers are the Rohn 25G and 45G. The 25G is a light-duty tower and the 45G is capable of carrying fairly large loads. The online Rohn catalog (see the References — the latest version 3 was released in 2015) has most of the information you'll need to plan an installation and is considered a "bible" of information for tower construction.

The primary risks associated with guyed towers are related to the guys themselves. Guy material, construction, termination, anchoring, and long-term maintenance must be done correctly to keep risks low. At the low end of the guyed tower category is the house-bracketed tower. In this case, the guyed tower sections are placed on a base immediately adjacent to a building, and specially designed brackets are used to support the tower. House brackets are required to be secured to the building in a structurally sound manner. Manufacturers can supply specifications. A local structural engineer can also provide custom plans designed specifically for the unique structure involved.

Fixed, self-supporting towers are made by several manufacturers and allow building a tower up to 100 feet or higher with a small footprint. Rohn, Trylon, and AN Wireless are popular vendors. In general, fixed self-supporting towers are reliable and long-lasting as long as the antenna load is kept well within the tower's specs and the tower is regularly inspected for corrosion. A self-supporting tower requires a substantial concrete base or footing.

Another type of self-supporting tower is the *crank-up*, shown in **Figure 28.11**. One large manufacturer of crank-up towers is US Towers. Using a system of cables, pulleys and winches, crank-up towers can extend from 20 feet to over 100 feet high. These are moderately complex devices, and as such, present certain risks. Because they consist of a variety of moving parts, crank-up towers require more maintenance than guyed or other self-supporting designs. As with the fixed, self-supporting tower, a crank-up tower requires a large concrete base.

Owners and climbers of crank-up towers must observe additional safety procedures to ensure that the mechanical state of the tower will not present risks during any operations that involve climbing. The tower sections should be fully nested and blocked ensuring there is no way for any of the sections to slip within the tower unexpectedly during work.

Antennas can also be installed on a *roof-mounted tower*, seen in **Figure 28.12**. These are four-legged aluminum structures of heights from four to more than 20 feet. While they are designed to be lag-screwed directly into the roof trusses, it is often preferable to through-bolt them into a long 2×4 or 2×6 that acts a backing plate, straddling and attached to three to four roof trusses. In any case, if it is not clear how best to install the tower on the structure, have a roofing professional or engineer provide advice. Working on a roof-mounted tower also requires extra caution because of climbing on a roof while also working on a tower. Many of these light-weight, aluminum towers cannot be climbed, so you must use a ladder to access the antenna. Again, extreme caution is required.

## 28.2.4 Tower Construction and Erection

### THE BASE

Once all the necessary materials and the required approvals have been gathered, tower installation can begin. Let's assume you and your friends are going to install it. The first job is to construct the base. A base for a guyed tower can be hand-dug as can the guy anchors. For a self-supporting tower, renting an excavator of some sort will make it much easier to move the several cubic yards of dirt.

In the bottom of the hole, be sure to add several inches of gravel or crushed stone that will allow water to drain from the hollow tower legs. If the base section is not going to sit on the gravel, be sure to provide a drainage path for the legs. Water that builds up in the tower legs from condensation or leakage will rust out the steel from the inside where it is not visible until significant damage has been done, creating a severe safety hazard. Similarly, standing water in the legs may also freeze and split the tubing with the same effect on safety.

Next, some sort of rebar cage will be needed for the concrete. Guyed towers only require rudimentary rebar while a self-supporting tower will need a bigger, heavier and more elaborate cage. Consult the manufacturer's specifications for the exact materials and dimensions. As noted earlier, documentation of how the base is constructed is important for future reference when the tower is maintained or removed. It may also be necessary for a building permit and inspection along with home and liability insurance.

Typical tower concrete specs call for 3000 psi (minimum) compressive strength concrete and 28 days for a full cure. (See the manufacturer's specifications.) A local premix concrete company can deliver it. Pouring the concrete is easiest if the concrete truck can back up to the hole. If that's not possible, a truck- or trailer-mounted line pump can

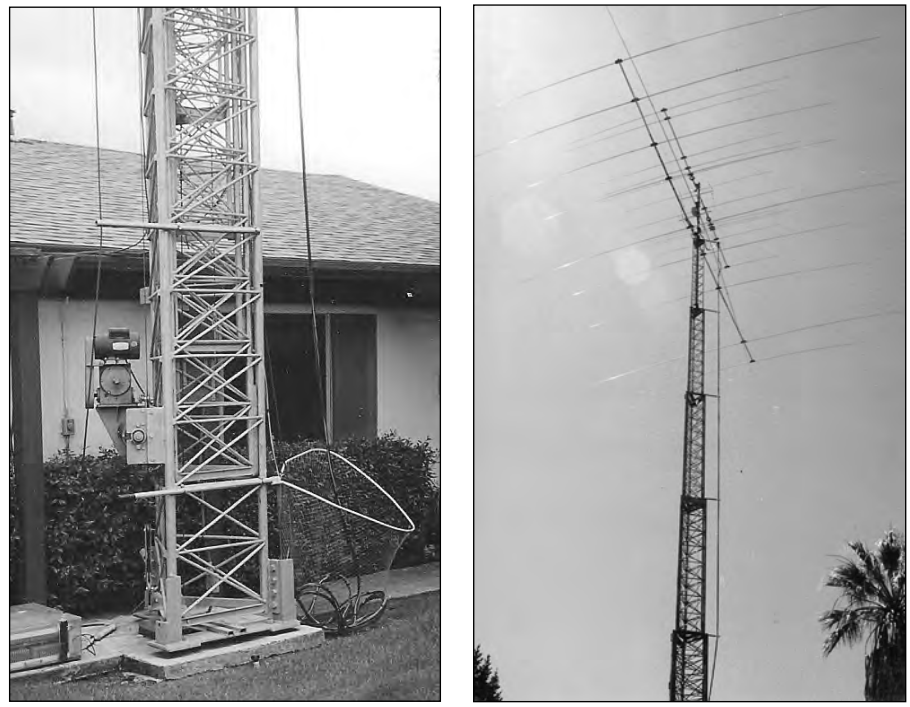

**Figure 28.11 — The bottom of N6TV's crank-up tower is shown at left. The motor drive mechanism is on the left and a fishing net on the right catches and coils the feed lines and control cables as the tower is lowered. On the right, K6KR's fully loaded crank-up extended to its maximum height of 90 feet. [Steve Morris, K7LXC, photos]**

**Figure 28.12 — The roof-mounted tower holding the AA2OW antenna system. [AA2OW photo]**

## Principles of Working Safely

The following safety tenets founded on three fundamental principles: Do it safely or not at all; There's always time to do it right; and If it's worth doing, do it better.

1. Never load or operate structures or equipment outside the design limits. Be careful with tools, ropes, pulleys, and other equipment that can cause injury or damage if they fail due to overload. Use the right stuff!

2. Always move to a safe, controlled condition and seek assistance when a situation is not understood. This is particularly important when working on towers and antennas. If something doesn't look right or isn't going according to plan, return to a safe state and figure out what to do.

3. Always operate with the safety mechanisms engaged. If a safety mechanism prevents you from doing something, either the task is unsafe or you may not be using the right equipment.

4. Always follow safe work practices and procedures. Make a plan before you start and don't do something you know is unsafe.

5. Act to stop unsafe practices. The team's safety depends on every team member. Do not hesitate to stop work if you see it is unsafe. Don't be afraid to speak up or ask for help! Regroup and do it right.

6. Clarify and understand procedures before proceeding. This is particularly important when working with a crew. Be sure everyone understands the procedure and how to communicate.

7. Involve people with expertise and firsthand knowledge in decisions and planning. Ask for advice and guidance from experienced hams when planning a task with which you are unfamiliar.

pump it up to 400 feet at minimal expense if using a wheelbarrow is not possible or practical. Packaged concrete from the hardware store mixed manually may also be used, but the volume of concrete required will typically make this a very substantial job. Quikrete Mix #1101 is rated at 2500 psi after seven days and 4000 psi after 28 days.

### TOOLS

Once the base and anchors are finished and the concrete has cured, the tower can be constructed. There are several tools that will make the job easier and safer. Since most hams do not build or climb towers on a regular basis, practice using all of the tools and accessories before starting a tower project. Know how to tie and untie basic knots. Practice lifting and lowering operations at ground level before attempting them at height.

If the tower is a guyed tower, it can be erected either with a crane (discussed in the section below on installation) or a *gin-pole*. The gin-pole, shown in **Figure 28.13**, is a pipe that attaches to the leg of the tower and has a pulley at the top for the haul rope. Use the gin-pole to pull up one section at a time (see below).

Another useful tool for rigging and hoisting is the *carabiner*. Shown in **Figure 28.14** (A and B), carabiners are oval steel or aluminum snap-links popularized by rock and mountain climbers. They have spring-loaded gates and can be used for many tower tasks. For instance, there should be one at the end of the haul rope for easy and quick attachment to rotators, parts, and tool buckets — virtually anything that needs to be raised or lowered. It can even act as a "third hand" on the tower. (Do not use light-duty carabiners marked "Not For Climbing.")

Pulleys ("blocks") are required for lifting and maneuvering loads with ropes. At a minimum, one pulley is needed for the haul rope at the top of the tower, and having two or more high-quality pulleys is usually required. Use pulleys rated for heavy loads such as for marine rigging and rock climbing. A *snatch block* is also useful; this is a pulley with one side that swivels so it can open up to "snatch" (attach to) the rope at any point without having to thread the rope through the pulley housing over the rotating sheave. **Figure 28.15** shows two snatch-block pulleys used for tower work.

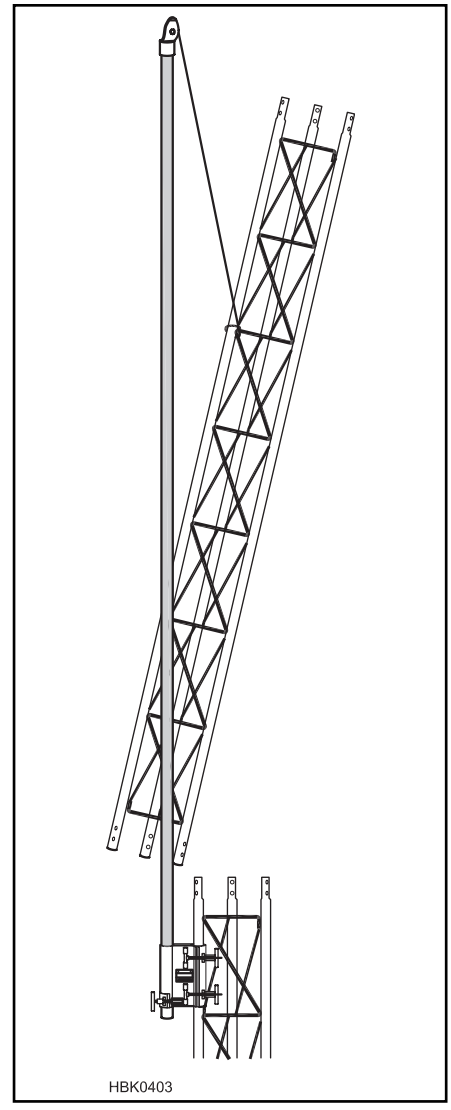
Winches and come-along devices can make life a lot easier during certain operations. They provide mechanical advantage to reduce the human force required for lifting and other tasks. Winches can be manually operated or electric. Electric winches can dramatically reduce physical effort and they can cut hours out of a big tower job but powered winches come with increased risks. It is often very difficult to assess the tension being applied by a powered winch. Practice and extra care are required when using these powered tools.

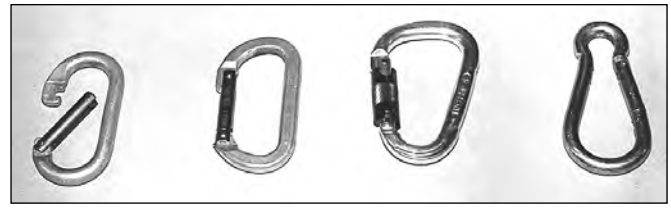
### ROPES AND SLINGS

The right number and types of ropes used in a tower project can have a dramatic impact on the time, effort and risks of a tower job. Experienced tower teams will employ several ropes to get the job done. It is quite common to use two ropes in most projects. The first is a utility rope. This rope goes straight up and down the tower through a pulley located at the location where work is being done. It is used to lift and lower tools and other small items.

The second rope is the haul rope. This rope will typically be one-half inch in diameter, or larger, and will afford a good grip for pulling and lifting the heavy items. **Table 28.2** shows the safe working load ratings for common types of rope.

There are several choices of rope material. The best choice is a synthetic material such as nylon or Dacron. A typical twisted rope is fine for most applications. A synthetic rope with a braid over the twisted core is known as *braid-on-braid* or *kernmantle*. While it's more expensive than twisted ropes, the outer





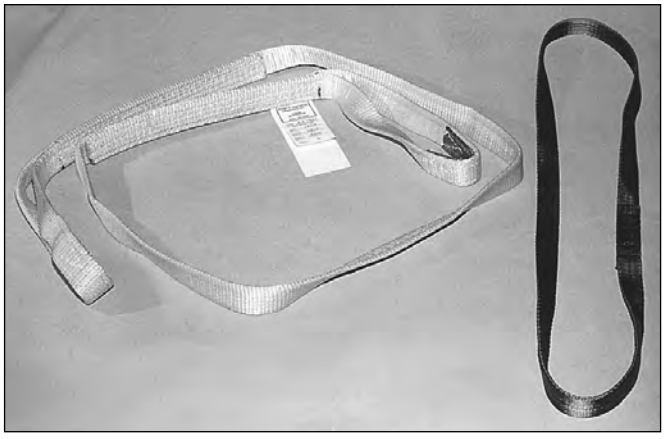


**Figure 28.13 — A gin-pole consists of a leg clamp fixture, a section of aluminum mast and a pulley. It is used to lift the tower section high enough to be safely lowered into place and attached. (Based on Rohn EF2545.)**

(B) An open aluminum oval carabiner; a closed oval carabiner; an aluminum locking carabiner; a steel snaplink. (C) A heavy duty nylon sling on the left for big jobs and a lighter-duty loop sling on the right for everything else. [Steve Morris, K7LXC, photos]**

**Figure 28.15 — Snatch blocks can be opened to place a rope directly on the sheave without having to thread it through the housing. A lightweight plastic block is shown at left, and two metal housing blocks at right.**

**Table 28.2**
**Rope Sizes and Safe Working Load Ratings in Pounds**

**3-Strand Twisted Line**

| *Diameter* | *Manila* | *Nylon* | *Dacron* | *Polypropylene* |
|---|---|---|---|---|
| ¼ | 120 | 180 | 180 | 210 |
| ⅜ | 215 | 405 | 405 | 455 |
| ½ | 420 | 700 | 700 | 710 |
| ⅝ | 700 | 1140 | 1100 | 1050 |

**Double-Braided Line**

| *Diameter* | *Nylon* | *Dacron* |
|---|---|---|
| ¼ | 420 | 350 |
| ⅜ | 960 | 750 |
| ½ | 1630 | 1400 |
| ⅝ | 2800 | 2400 |

braid provides better abrasion resistance.

The least expensive type of rope is polypropylene. While it is reasonably durable and cheap, it's a stiff rope that doesn't take a knot as well as other types. Polypropylene is also subject to breakdown over time due to exposure to natural ultraviolet in sunlight. These factors can present real safety risks; it's best to use a higher quality rope.

Two factors that can come into play when selecting a rope are the elasticity and flexibility of the rope. A more elastic rope will stretch when under load. This can be a helpful characteristic when a shock-absorbing feel is desired. It is not helpful when it is important to maintain the rope's position. Flexibility is a generally good feature, allowing the rope to be more easily maneuvered and tied.

When doing tower work, being able to tie knots is required. Of all the knots, the *bowline* is the one to know for tower work. Most amateurs are knot-challenged so it's a great advantage to know at least the bowline and various hitches. You can learn how to tie many useful knots **www.animatedknots.com**.

The *loop sling* in Figure 28.14C can be wrapped around large or irregularly shaped objects such as antennas, masts or rotators, and attached to ropes with carabiners. For a complex job, a professional will often climb with eight to ten slings and use every one!

Web slings are typically made of nylon webbing and come in a variety of lengths and load ratings. The smallest are a few inches long, with 1/2-inch wide webbing, and rated for a few hundred pounds. Large slings are several feet long and rated at a few thousand pounds. They are typically wrapped around the load, such as a mast, or through a hole or section of a load like a tower section. A carabiner around the webbing is used to create a lift point for the sling. There are a variety of "hitches" used for different load shapes and orientations.

### INSTALLING TOWER SECTIONS

The easiest way to erect a tower is to use a crane or boom truck, such as used for putting up signs. It's fast and safe but more expensive than doing it in sections by hand. A crane or boom-truck from a sign company, for example, allows a tower to be constructed on the ground and lifted into place either in one piece or in sections. The crane can hold loads indefinitely while the climbers take as much time as needed to deal with the heavy sections. A crane can also lift an antenna clear of guys and other antennas, avoiding a lot of rope work by the climbers and ground crew.

The crane operator will need access to stable ground near the tower base and clearance to move the tower around. The tower is picked up or "picked" using a heavy web sling attached above the tower's center of gravity so that it will hang vertically in a stable configuration. Pre-assemble and install guys on the tower so they can be secured before the crane sling is released. A crew guides the bottom of the tower onto the base with the crane holding the weight, then secures the base followed by attaching the sets of guys.

To erect a tower by sections, a gin-pole is needed (see Figure 28.13). It consists of two pieces — a clamp or some device to attach it to the tower leg and a pole with a pulley at the top. The pole is typically longer than the work piece being hoisted, allowing it to be held above the tower top while being attached or manipulated.

With the gin-pole mounted on the tower, the haul rope runs up from the ground, through the gin-pole mast and pulley at the top of the gin-pole, and back down to the load. The haul rope has a knot (preferably a bowline) on the end for attaching things to be hauled up or down. A carabiner hooked into the bight of the knot can be attached to objects quickly so that you don't have to untie and re-tie the bowline with every use.

It's a good idea to pass the haul rope through a snatch-block at the bottom of the tower, changing the direction of the rope from vertical to horizontal. This allows the ground crew to pull horizontally. It also provides them an easier view up the tower and keeps them away from the tower base, in case the climbers accidently drop something.

### GUYS

For guyed towers, it's the guys that do the work of keeping the tower where it should be under working load and the stresses of weather. Important construction parameters are *guy wire material* and *guy tension*. Do *not* use rope or any other material not rated for use as guy cable as tower guys — even during tower erection. Guyed towers for amateurs typically use either 3⁄16-inch or ¼-inch *EHS* (extra high strength) steel guy cable.

There are also several commercially manufactured non-metallic cables designed to support towers. The most popular and well-tested in the amateur radio market is Phillystran, a lightweight cable made of Kevlar fibers. Phillystran is available with breaking strength similar to EHS cable. The advantage of Phillystran is that it is non-conducting and does not create unwanted electrical interaction with antennas on the tower. It is an excellent choice for towers supporting multiple Yagi and wire antennas and does not have to be broken up into short lengths with insulators.

EHS wire is very stiff — to cut it, use a hand-grinder with thin cutting blades or a circular saw with a metal-cutting aggregate blade. Wear safety glasses and gloves when cutting since there will be lots of sparks of burning steel being thrown off. Phillystran can be cut with a utility knife or a hot knife for cutting plastic. Because Phillystran can be melted or cut, if there is a risk of fire or vandalism, the bottom section of the guy should be EHS.

Guys should be tightened to the manufacturer's specifications. If the guys are too loose, the result will be wind-induced shock loading. Guys that are too tight exert extra compressive load on the tower legs, reducing the overall capacity and reliability of the tower. The proper tension for EHS or Phillystran guys is 10% of the material's *ultimate breaking strength*. For 3⁄16-inch EHS the ultimate breaking strength is 4900 pounds, and for ¼-inch it's 6000 pounds, so the respective guy tension should be 490 pounds and 600 pounds. The easiest to use, most accurate, and least expensive way to measure guy tension is by using a Loos tension gauge, developed for sailboat rigging (**loosnaples.com/tension-gauges**).

Guy wires used to be terminated in a loop with cable clamps, but those have been largely replaced by pre-formed Big Grips, shown in **Figure 28.16**. These simply twist onto the guy wire and are very secure. They grip the guy cable by squeezing the cable as tension is applied. Be sure to use the right type of Big Grips for the thickness and material of the guy cable. It is also tempting to reuse Big Grips. A limited number of reapplications is permitted by the manufacturer before a grip should be taken out of service. Users should check manufacturer's guidelines for details.

## 28.2.5 Antenna Installation

Once the tower is up, it's time to install the antennas. VHF/UHF whips and HF wire antennas are pretty straightforward, but installing an HF Yagi is a more challenging project. With a self-supporting tower, there are no guy wires to contend with — generally, the antenna can just be hauled up the tower face. Sometimes it is simply that easy!

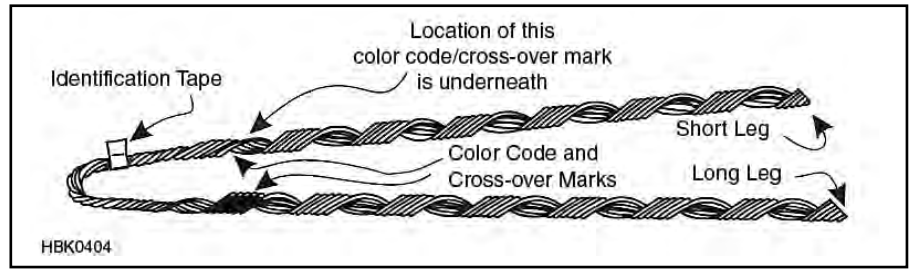
In most cases, short of hiring a crane, the preferred way to get a Yagi up and down a tower is to use the *tram* method. A single tramline above or between the top guys is suspended from the tower to the ground and the load is suspended under the tramline. **Figure 28.17** illustrates the tram method of raising antennas.

The tram line is typically attached to the mast above the top of the tower. In the case of a big load, the line may exert enough force to bend the mast. If in doubt, *back-guy* the mast with another line in the opposite direction for added support.

### MASTS

A mast is a pipe that sticks out of the top of the tower and connects the rotator to the antenna. For small antenna loads and moderate wind speeds, any pipe will work. But as wind speed and wind load increase, more force will be exerted on the mast. Selecting a mast that's up to the job is an extremely important design consideration. There is no tower operation more risky and potentially more expensive than recovering from a bent mast.

There are two materials used for masts — *pipe* and *tubing*. Tubing is designed to carry structural loads and should be used for large antennas or multiple antennas above the tower. Pipe can be water pipe or conduit (EMT). Pipe is a heavy material with not much strength since its job is just to carry water or wires. Pipe is acceptable as mast



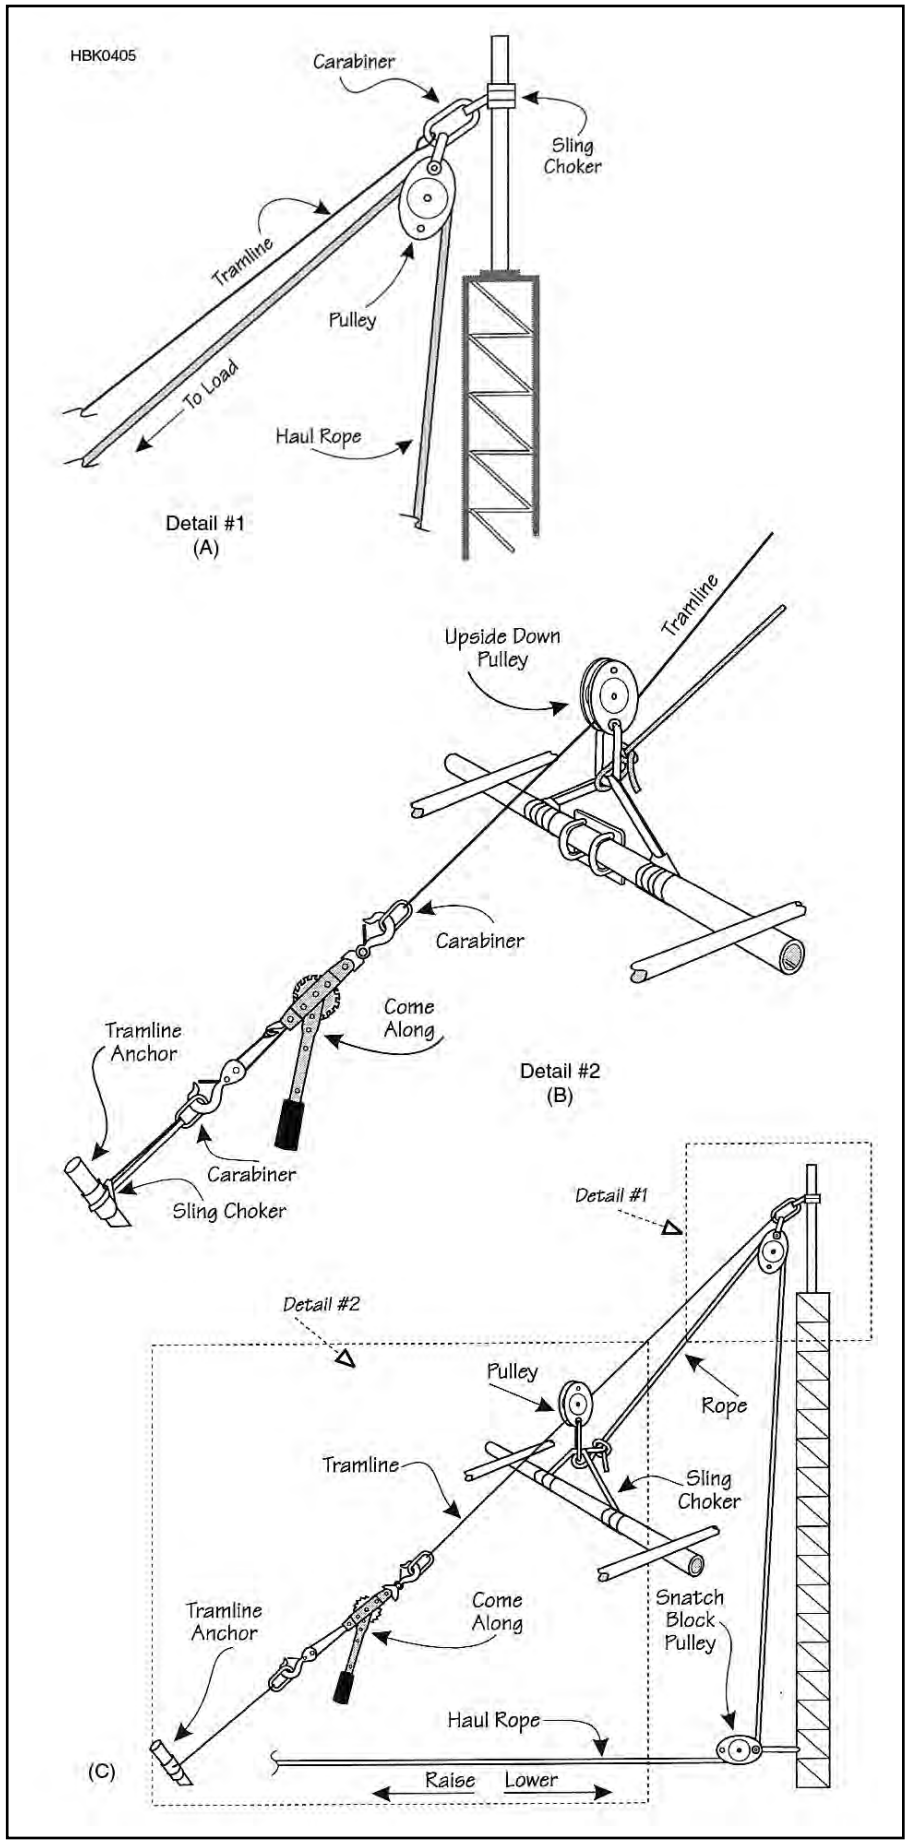


**Figure 28.16 — A PreFormed Line Products Big Grip for guy wires.**

material for small loads only. Another problem is that 1.5-inch pipe (pipe is measured by its inside diameter or ID) is only 1.9-inches OD. Since most antenna boom-to-mast hardware is designed for a 2-inch mast, the less-than-perfect fit may lead to slippage.

For any larger load, carbon-alloy steel tubing rated for high strength is highly recommended. A moderate antenna installation in an 80 MPH wind might exert 40,000 to 50,000 pounds per square inch (psi) on the mast. Pipe has a yield strength of about 35,000 psi, so you can see that pipe is not adequately rated for this type of use. Chromoly (short for *chromium-molybdenum* alloy) steel tubing is available with yield strengths from 40,000 psi up to 115,000 psi but it is expensive. **Table 28.3** shows the ratings of several materials used as masts for amateur radio antennas.

Calculating the required mast strength can be done by using a software program such as the *Mast, Antenna and Rotator Calculator (MARC)* software. (See the References.) The software requires as inputs the local wind speed, antenna wind load, and placement on the mast. The software then calculates the mast bending moment and will recommend a suitable mast material.

## 28.2.6 Climbing Safety

Working at height is a potentially dangerous activity. As you think about climbing a roof or a tree or a tower, it is important to frame every decision in the context of safety. Continually asking the question, "Is this the safest way?" should become second nature. In the workplace this is known as developing a *safety mindset*. Mature organizations and teams build safety considerations into every project they undertake, fully recognizing the costs in time and resources that come with keeping people and property safe. The world of amateur radio is no different. Payback on investments in safety is returned over the long term, manifest in reduced rates of injury and fatalities. Developing a reputation as a safe pursuit also helps to foster the necessary trust for us to pursue the experimental aspects of amateur radio.

In this section, we will focus on tower

**Figure 28.17 — At A, rigging the top of the tower for tramming antennas. Note the use of a sling and carabiner. (B) Rigging the anchor of the tramline. A come-along is used to tension the tramline. (C) The tram system for getting antennas up and down. Run the antenna part way up the tramline for testing before installation. It just takes a couple of minutes to run an antenna up or down once the tramline is rigged.**

**Table 28.3**
**Yield Strengths of Mast Materials**

| *Material* | *Specification* | *Yield Strength (lb/in.²)* |
|---|---|---|
| Drawn aluminum tube | 6063-T5 | 15,000 |
| | 6063-T832 | 35,000 |
| | 6061-T6 | 35,000 |
| | 6063-T835 | 40,000 |
| | 2024-T3 | 42,000 |
| Aluminum pipe | 6063-T6 | 25,000 |
| | 6061-T6 | 35,000 |
| Extruded alum. tube | 7075-T6 | 70,000 |
| Aluminum sheet and plate | 3003-H14 | 17,000 |
| | 5052-H32 | 22,000 |
| | 6061-T6 | 35,000 |
| Structural steel | A36 | 33,000 |
| Carbon steel, cold drawn | 1016 | 50,000 |
| | 1022 | 58,000 |
| | 1027 | 70,000 |
| | 1041 | 87,000 |
| | 1144 | 90,000 |
| Alloy steel | 2330 cold drawn | 119,000 |
| | 4130 cold worked | 75,000 |
| | 4340 1550 °F quench 1000 °F temper | 162,000 |
| Stainless steel | AISI 405 cold worked | 70,000 |
| | AISI 440C heat-treated | 275,000 |

(From *Physical Design of Yagi Antennas* by David B. Leeson, W6NL)

climbing, but many of the concepts are transferable to other forms of work aloft such as on roofs and in trees which all have their own safety risks.

## TAKE ADVANTAGE OF STANDARDS

Standards organizations provide a great deal of guidance in the area of safety equipment and technique. In the United States, OSHA, the Federal Occupational Safety and Health Administration, collects and analyzes real-world safety data. The agency then works with industry to create and publish high-level regulations for workplace safety. These rules include minimum standards for equipment and procedures. ANSI (American National Standards Institute) is an independent non-profit organization that encourages further development of detailed requirements for safety in many areas, including tower safety. The Telecommunication Industry Association (TIA) produces the most widely accepted standards package covering tower safety — currently at revision ANSI/TIA-222-H in early 2021.

Although amateurs working on their own non-commercial projects without compensation are not bound by these rules and recommendations, you'll be much better off by following them. There are many suppliers of excellent safety equipment that meets and exceeds the industry standards. As long as you choose compliant equipment and learn safe techniques, you will be on the path to a safe and successful project.

## BEFORE YOU BEGIN: PREPARATION

As you contemplate any new project, you will need to define the scope of the entire job.

- What are your goals?
- How will you define success?
- What strategies could you use to achieve the goals?

Consider a job that's diagnostic. You believe there is a problem with a coaxial cable getting hung up on some tower hardware. The goal is to observe the coax as you turn the antenna rotor through 360 degrees of rotation. The traditional approach would be to send a climber up the tower for direct, close-up observation. But new technology can offer faster, easier, and safer options. Consider observing with binoculars from the safety of the ground or an upper floor in a nearby building. Or send a drone right to the location in question and capture recorded video through the full rotation.

Another concept that can greatly reduce risks and make a job go more smoothly is to break the work down into well-defined modules. Successful completion of one module should be required before proceeding to the next. When you break the work down this way, you gain the ability to manage your time more precisely and you have a built-in series of go/no-go decision points.

When you decide that climbing is the right approach, take stock of all elements of the job.

- Skills and experience
- Parts and supplies
- Safety equipment
- Tools
- People
- Time
- Conditions (weather, physical impediments, safety status)

One of the most important aspects of safety that you must assess is whether you have the knowledge and awareness to do a job safely and efficiently. You must have the mental ability to climb and work at altitude while constantly rethinking all connections, techniques and safety factors. Safely climbing and working on towers is 90% mental. Mental preparedness is something that must be learned. This is an occasion where there is no substitute for experience. Establishing and maintaining the right mental attitude is the hardest step for most people, but when safety gets the focus it deserves, tower work can be done safely and accidents are relatively rare.

## PRE-CLIMB SAFETY INSPECTION

Before climbing any tower, perform a careful inspection of the base, anchors, and guys. A pair of binoculars allows inspection of the tower and guys above eye level. There should be no visible rust on the base section, especially where it contacts concrete. Look for splits from water freezing in the tower legs. If any of these are apparent, do not climb until further checks and any repairs are done. A small hole (⅛ inch typically) may be drilled in the bottom of a tower leg without compromising strength in order to drain any standing water. Guys should be correctly tensioned and all guy attachments and anchors secure and free of rust.

If the tower is a crank-up model, lower it completely until the lift cable is slack. Tower sections can bind and appear to be lowered completely but slip from a climber's weight, causing serious injury. Before climbing, block all tower sections with a 2×4 or heavier material through the tower so that no downward motion is possible. Never assume a crank-up tower is fully nested.

For tilt-over towers or tower-lowering fixtures, perform a careful inspection of the winch, cable, and fixture before raising or lowering the tower. When the tower is near horizontal, the tension in the cable can be thousands of pounds. Make sure no one is near the tower as it is raised or lowered and wear protective gear when operating the winch.

## 100% TIE-OFF: A RULE TO LIVE BY

Since its inception in the 1970s, OSHA has focused on workplace safety. In the 1980s, OSHA introduced the *100% tie-off* standard requiring a worker's body belt to be secured by at least two lanyards. This protection factor became an essential for employees

who executed tasks at height. Fortunately, the body belt soon evolved into a full harness, which further protected workers from spinal and internal organ injuries.

OSHA's fall protection standards even cover fall protection for residential construction projects. Personal fall arrest systems must bring a worker to a complete and controlled stop, restrict workers from falling more than 6 feet, and have the strength necessary to endure twice the impact energy of the worker falling 6 feet.

Why is this type of system necessary? 100% tie-off is part of your plan to "expect the unexpected." While you can be in top physical condition, equipped with the most modern tools and trained in the latest techniques, unexpected situations still arise. When everything is going well, there is no reason to expect to suddenly "just let go" when perched on the side of the tower. But, workers can and do experience sudden health emergencies. A heart attack or a fainting episode due to dehydration can render a worker unconscious. Unavoidable distractions can occur, as well. What if you were to accidentally disturb a bee or wasp nest and suddenly get stung while in your work position? Any of these situations could cause you to lose consciousness or the attention needed to maintain your footing. In moments like these, your 100% tie-off will save your life.

Fall protection is continuing to evolve in today's workplace, as employers and regulators seek new ways to protect workers. OSHA has ongoing research on how to identify hazards and is also improving current regulations. As a ham, if you know and take to heart the concept of 100% tie-off, you will be well on your way to making your tower work as safe as possible. Done right, climbing can be enjoyable, rewarding and safe as shown by Marty, NN1C and Jim, K1IR in **Figure 28.18**.

**Figure 28.18 — Marty, NN1C (left) and Jim, K1IR are fully equipped with the right climbing gear and tools for tower and antenna work. (Jim Idelson, K1IR, photo)**

## PERSONAL SAFETY EQUIPMENT

To implement 100% tie-off, you need the right equipment. OSHA specifies the equipment that must be used. Minimum requirements for Personal Protective Equipment (PPE) are given in OSHA Standard 1910.140 - Personal fall protection systems (**www.osha.gov/laws-regs/regulations/standardnumber/1910/1910.140**). *DO NOT* cut corners on buying or using safety equipment; you bet your life on it every time you use it! **Figure 28.19** shows a typical set of climbing and safety gear used when working on towers.

The most important pieces of safety equipment are the *personal fall arrest system* (PFAS) you wear and the accompanying lanyards that attach to it. **Figures 28.20A** and **B** show a climber wearing a PFAS from the front and back. The body harness portion of the PFAS has leg loops and suspenders to

**Figure 28.19 — Typical climbing equipment. From the top, left-to-right, fall arrest lanyards with "gorilla hooks", hard hat and safety glasses, body harness, gloves, nylon sling, carabiners, and positioning lanyard. (Jim Idelson, K1IR, photo)**

(A) (B)

**Figure 28.20 — The personal fall arrest system (PFAS) from the front (A) and back (B). Note that tools and slings are attached in the back where they will not interfere with the positioning lanyard. (Jim Idelson, K1IR, photos)**

help spread the fall forces over more of your body and has the ability to hold you in a natural position with your arms and legs hanging below you where you're able to breathe normally. (See the warning below about lineman belts.)

Two or more lanyards are used. The first is the fall arrest lanyard (top item in Figure 28.19) which attaches to a D-ring between your shoulder blades. The other ends are attached to large snap hooks ("gorilla hooks") that clip on to the tower above the work or climbing position. The proper choice is a dual shock absorbing lanyard with bar-tacked stitches that pull apart under force to catch and decelerate you in case of a fall A simple 6-foot rope lanyard is inexpensive but doesn't offer any shock absorption and does not provide 100% tie-off.

The second lanyard is a positioning lanyard (bottom item in Figure 28.19) that holds you in working position and attaches to the D-rings at your waist. It can be adjustable or fixed and may be made from different materials such as nylon rope, steel chain, or special synthetic materials. An adjustable positioning lanyard as shown in the figure will adjust to almost any situation, whereas a fixed-length one is typically either too long or too short. A rope lanyard is the least expensive. **Figure 28.21A** shows a climber with a positioning lanyard around the tower and the fall arrest lanyards both attached to the tower with one above him. This is a safe working position.

Hams should note that leather climbing equipment was outlawed some years ago by OSHA — so don't use it. This includes the old-fashioned safety belt that utility linemen used for years but which offers no fall protection capability. If you drop down while wearing a safety belt, your body weight can cause it to rise up from your waist to your ribcage where it could immobilize your diaphragm and suffocate you. On the other hand, you can use a safety belt for positioning when it's worn in conjunction with a compliant FAH. In fact, most modern fall arrest harnesses also incorporate a waist belt with positioning lanyard attachment rings for a single, convenient, comfortable climber safety package.

But having the right gear doesn't ensure it is in good working order. Take a page from the OSHA regulations: professional tower workers are required to check their safety equipment every day. Make it your habit to check your safety equipment before you use it every time. Inspect for any nicks or cuts to your harness and lanyards immediately prior to each use.

## DRESS FOR SUCCESS

You'll want to equip yourself with some additional gear for a safe and compliant climb:

Boots should be leather with a steel or fiberglass shank. Diagonal bracing on Rohn 25G is only 5⁄16 inch rod — spending all day standing on that narrow support will take a toll on your feet. The stiff shank will support your weight and protect your feet; tennis shoes will not. Leather boots are mandatory on towers like Rohn BX that have sharp X-cross braces. Your feet are always on a slant and against a sharp angle of sheet metal — that is hard on feet.

A hard hat and safety goggles are both required and highly recommended. Make sure they are ANSI or OSHA approved and that you and your crew wear them. As you'll be looking up and down a lot, a chin strap is essential to keep the hard hat from falling or blowing off. You may not need the safety goggles until you are at the work position but have them available in your tool kit.

Tower work can be hard on hands, especially if you don't work on towers frequently. Gloves are essential — keep several spare pairs for ground crew members who show up without them. Cotton gloves are fine for gardening but not for tower work; they don't provide enough friction for climbing or working with a haul rope. Gloves designed for the job and the environment are the only kind to use. You will find a range of options made from leather and other synthetic materials that are up to the job. The softer the gloves, the more useful they'll be during intricate parts of the job. Framer's gloves with the tips of the thumb and first two fingers removed protect the palm and back of the hand while allowing fine fingertip control but expose fingers to cold weather. You will need warmer gloves if you are doing a job in cold weather. The bottom line is that you should maintain a selection of gloves that give you the right combination of gripping power, dexterity, and warmth to handle all the different jobs and weather you will encounter.

(A) (B) (C)

**Figure 28.21 — Proper 100% tie-off technique (see text). Lanyard attachment at the work position is shown in A. Getting ready to climb with both fall-arrest lanyards attached is shown at B. Moving one of the fall arrest lanyards while maintaining tie-off is shown at C. (Jim Idelson, K1IR, photos)**

## TOWER CLIMBING BEST PRACTICES

Just having the right gear does not ensure that it will save your life; you have to use it correctly. The most important rule for using a full body harness and dual fall arrest lanyard is to follow these 100% tie-off steps as you climb. Figures 28.21B and C show the proper way to climb while maintaining 100% tie-off.

1) Attach one lanyard hook above you as you start your ascent.

2) In the case of most ham towers, attach to a tower leg, as the leg provides the strongest anchor point. A tower rung may not be strong enough to sustain the downward force of a fall as specified in the OSHA requirements.

3) As you climb, attach the second lanyard hook to a tower leg a few feet above the first. It helps to repeat "On before off" so you remember reinforce doing things in the proper order.

4) Disconnect the lower hook and continue to climb.

5) As you climb, alternately place the hooks such that you are always securely connected by one of lanyard ends and try to keep your attachment point above you as much as possible. This will limit the maximum distance you can fall at any moment.

6) When you reach your work position, attach both lanyards above you for redundant fall protection while you do the job.

7) Reverse these steps as you descend.

Note that the sequence described above does not call for use of a positioning lanyard. That is because, while a positioning lanyard is helpful in providing comfort while climbing or while working, it does not meet the stringent requirements for fall arrest. So, you can — and should — use positioning lanyards to make your work easier, but don't depend on them for fall protection.

Many climbers have developed ways of thinking about movement on a tower that force safer behavior. One such model is the concept of having four points of attachment and security — two hands and two feet. When climbing, move only one point at a time. That leaves you with three points of contact and a wide margin of safety if you ever need it. This is in addition to having your fall-arrest lanyard connected at all times.

Another recommended technique is to always do everything the same way every time. That is, always wear your positioning lanyard on the same D-ring and always connect it in the same way. Always look at your belt D-ring while clipping in with your safety strap to confirm that you're securely attached. A visual check helps ensure you are connected to a D-ring and not some other piece of gear. Always look!

## SAFETY TIPS

1) Don't climb with anything in your hands; attach it to your safety belt if you must climb with it, or have your ground crew send it up to you in a bucket.

2) Don't put any hardware in your mouth; it can easily be swallowed.

3) Don't climb while wearing rings and/or neck chains; they can get hooked on things.

Long hair should be secured.

4) Be on the lookout for bees, wasps, hornets, and their nests. If you do run into a stinging insect, use Adolph's Meat Tenderizer on the sting — it contains the enzyme papain which neutralizes the venom. Have a small jar in your tool kit.

5) Don't climb when tired; that's when most accidents occur.

6) Don't try to lift anything by yourself; one person on a tower has very little leverage or strength. Let the ground crew use their strength; save yours for when you really need it.

7) If a procedure doesn't work, assess the situation and re-rig, if necessary, before trying again.

### A TEAM EFFORT: CLIMBERS + GROUND CREW

Every antenna or tower project is a team effort, and the ground crew is critical to a successful outcome. Don't underestimate the impact the ground crew will have on your project. Consider these points when you put together your support team.

1) Put together a team that has the right mix of skills. If you are going to be tramming an antenna, the ground crew should know how to do it.

2) Make sure the team is committed to the job. Commitment means staying for the duration and not being distracted while the job is under way.

3) Communication is critical. The ground crew should be equipped to communicate with the tower climber(s) with appropriate gear. Many teams use handheld VHF or FRS radios for this purpose.

4) Tools are a major responsibility for the ground crew. Climbers should only need to do the minimum amount of climbing necessary to get the job done. Ground crew need to know where to find a needed tool and have a way to get it into the hands of a climber quickly. Ground crew will also need to be fully up-to-speed on operation of specialized tools like the gin pole, come-along, and winches.

### WORKING AS A TEAM

Before tower work starts, have a safety meeting with the ground crew. This "tailgate" meeting is important to get everyone on the same page, work-wise, detailing the work to be done and how to do it. This also the time and place to introduce the ground crew to gear or hardware they may be unfamiliar with such as a capstan winch, carabiners, rock climbing gear, special tools, and so on. Explain what is going to be done and how to do it.

The climber(s) are frequently the most experienced members of the tower team. As such, one of the climbers is usually designated to be the team leader. This leadership role is critical for everyone to understand. The climber(s) are most at risk and often have a unique visual perspective on what's happening at any moment. It's very important for the team to stay focused on the job and to be actively listening for instruction from the climbers. There can be long stretches of work that only involves the climbers, but a need for ground crew support can arise in an instant and the team needs to be ready to respond immediately. Remember, don't do anything unless directed by the leader in charge. This includes handling ropes, tidying up, moving hardware, and so on.

Another important role for the ground crew is to communicate updates and any other information that can be helpful to the team on the tower. As a climber, it is very helpful to hear about anything that might affect upcoming actions or decisions. This might include notifications about changing weather, changes in the ground crew, updates regarding supplies or parts of the project being handled on the ground. Let the tower crew know when it's time to break for lunch!

If radios are not being used to communicate, when talking to the climber on the tower, look up and talk directly to them in a loud voice. The ambient noise level is significantly higher up on the tower because of traffic, wind and nearby equipment. Have an agreed-on set of hand signals for raising, lowering, holding, starting and stopping, etc.

While leadership generally comes from the climber, it is very important for all team members to understand that responsibility for watching for safety issues belongs to everyone. Any team member who senses an impending safety risk should raise the issue right away. The team should respect any safety-related observation, pause, and evaluate the situation. The team should then decide what to do. Action should only be taken when the team has determined best right course to pursue.

Be conservative throughout the course of the job. Operate slowly; trying to go too fast can result in poor work and cutting corners on safety.

### WRAPPING UP

When is it time to quit? We start all these projects with the goal of finishing up when the job is done, when the project goals have been met, and all within the planned time frame. But, despite the best of planning, complex jobs often take longer than expected. The question every antenna team will invariably face is what to do when it is becoming clear that the project can't be completed as planned. Sometimes it's a matter of running out of daylight. Or the weather is changing. Perhaps some members of the team have to leave. Or fatigue is setting in after a long day of work. Decisions made in these moments can be the difference between success and disaster.

The temptation is to work faster, to try to squeeze the rest of the job into the allotted time. This is a recipe for failure. Many accidents happen during just these circumstances. It is far better to choose a path that allows for securing the site in a safe state, getting the climbing team safely back on the ground and preparing to complete the job at the next opportunity. All this wind-down effort takes time, so the experienced crew should be anticipating the best point to suspend work, leaving sufficient time to wrap things up.

# 28.3 RF Safety

Amateur Radio is basically a safe activity. In recent years, however, there has been considerable discussion and concern about the possible hazards of electromagnetic fields (EMF), including both RF energy and power frequency (50-60 Hz) EMF. FCC regulations set limits on the maximum permissible exposure (MPE) allowed from the operation of radio transmitters. Following these regulations, along with the use of good RF practices, will make your station as safe as possible. This section, written by the ARRL RF Safety Committee (see sidebar), deals with the topic of electromagnetic safety.

## 28.3.1 How EMF Affects Mammalian Tissue

All life on Earth has adapted to live in an environment of weak, natural, low frequency electromagnetic fields, in addition to the Earth's static geomagnetic field. Natural low-frequency EM fields come from two main sources: the sun and thunderstorm activity. During the past 100 years, man-made fields at much higher intensities and with different spectral distributions have altered our EM background. Researchers continue to look at the effects of RF exposure over a wide range of frequencies and levels.

Both RF and power frequency fields are classified as *nonionizing radiation* because the frequency is too low for there to be enough photon energy to ionize atoms. *Ionizing radiation*, such as X-rays, gamma rays and some ultraviolet radiation, has enough energy to knock electrons loose from atoms. When this happens, positive and negative *ions* are formed. Still, at sufficiently high power densities, nonionizing EMF poses certain health hazards.

It has been known since the early days of radio that RF energy can cause injuries by heating body tissue. Anyone who has ever touched an improperly grounded radio chassis or energized antenna and received an *RF burn* will agree that this type of injury can be quite painful. Excessive RF heating of the male reproductive organs can cause sterility by damaging sperm. Other health problems also can result from RF heating. These heat related health hazards are called *thermal effects*. A microwave oven is an application that puts thermal effects to practical use.

There also have been observations of changes in physiological function in the presence of RF energy levels that are too low to cause heating. These functions generally return to normal when the field is removed. Although research is ongoing, no harmful health consequences have been linked to these changes.

In addition to the ongoing research, much else has been done to address this issue. For example, FCC regulations set limits on exposure from radio transmitters. The Institute of Electrical and Electronics Engineers, the American National Standards Institute and the National Council for Radiation Protection and Measurement, among others, have recommended voluntary guidelines to limit human exposure to RF energy. The ARRL maintains an RF Safety Committee, consisting of concerned scientists and medical doctors, who volunteer to serve the radio amateur community to monitor scientific research and to recommend safe practices.

### THERMAL EFFECTS OF RF ENERGY

Body tissues that are subjected to *very high* levels of RF energy may suffer serious heat damage. These effects depend on the frequency of the energy, the power density of the RF field that strikes the body and factors such as the polarization of the wave and the grounding of the body.

At frequencies near the body's natural resonances RF energy is absorbed more efficiently. In adults, the primary resonance frequency is usually about 35 MHz if the person is grounded, and about 70 MHz if insulated from the ground. Various body parts are resonant at different frequencies. Body size thus determines the frequency at which most RF energy is absorbed. As the frequency is moved farther from resonance, RF energy absorption becomes less efficient. *Specific absorption rate (SAR)* is a measure that takes variables such as resonance into account to describe the rate at which RF energy is absorbed in tissue, typically measured in watts per kilogram of tissue (W/kg).

*Maximum permissible exposure* (MPE) limits define the maximum electric and magnetic field strengths, and the plane-wave equivalent power densities associated with these fields, that a person may be exposed to without harmful effect, and are based on whole-body SAR safety levels. The safe exposure limits vary with frequency as the efficiency of absorption changes. The MPE limits Safety factors are included to insure that the MPE field strength will never result in an unsafe SAR.

Thermal effects of RF energy are usually not a major concern for most radio amateurs because the power levels normally used tend to be low and the intermittent nature of most amateur transmissions decreases total exposure. Amateurs spend more time listening than transmitting and many amateur transmissions such as CW and SSB use low-duty-cycle modes. With FM or RTTY, though, the RF is present continuously at its maximum level during each transmission. It is rare for radio amateurs to be subjected to RF fields strong enough to produce thermal effects, unless they are close to an energized antenna or unshielded power amplifier. Specific suggestions for avoiding excessive exposure are offered later in this chapter.

### ATHERMAL EFFECTS OF EMF

Biological effects resulting from exposure to power levels of RF energy that do not generate measurable heat are called *athermal effects*. A number of athermal effects of EMF exposure on biological tissue have been seen in the laboratory. However, to date all athermal effects that have been discovered have

## The ARRL RF Safety Committee

Imagine you wake up one day and the newspaper headlines are screaming that scientists have discovered radio waves cause cancer. How would you react? How would your neighbor react? You may not have to imagine very hard because the news has been inundated with this type of story regularly over the past couple of decades. Clearly our society has not been decimated by epidemics of diseases since the vast increase in cellular telephone use. Some people deal with this discrepancy by ignoring all scientific reports. Others adopt a pessimistic attitude that technology is going to kill us all eventually, while still others treat every such story as "the truth" and militantly try to stop the transmission of RF energy. The reality is that while all scientific study is complex, the study of electromagnetic biological effects is even more so. Few newspaper reporters are capable of understanding the nuances of a scientific study and are even less able to properly report its results to the lay public. As a result many newspaper stories mislead the public into thinking that a scientific study has found something about which they need to be warned.

The ARRL has dealt with this dilemma by creating the RF Safety Committee, a group of experts in the facets of medical, scientific and engineering investigation needed to fully critique and understand the results of studies on electromagnetic biological effects. Experts in Dosimetry, Public Health, Epidemiology, Statistical Methods, General Medicine and specific diseases are well suited to reading and understanding published scientific reports and critiquing their validity.

It is not uncommon to examine how an experiment was performed only to realize that errors were made in the design of the experiment or the interpretation of its results. It takes a group of reviewers with a wide range of expertise to consider the implications of all aspects of the study to recognize the value of the results.

The field of biological effects of electromagnetic energy constitutes a complex combination of scientific disciplines. Many scientific studies in this field do not generate reliable results because they are not based on input from experts in the many fields that affect the interactions between electromagnetic energy and biological organisms. Even well designed scientific studies are subject to misinterpretation when the results are presented to a public that does not understand or appreciate the complex interactions that occur between the physical world and biological organisms and how these affect public health.

Since the 1960s there have been thousands of scientific studies that were intended to discover if electromagnetic energy had an adverse affect on biological tissue. A large number of these studies, designed and performed by biologists, did not accurately expose the subjects to known levels of electromagnetic energy. A field of expertise in RF engineering, called dosimetry, was developed to accurately determine the exact field strengths of both electrical and magnetic fields to which subjects were exposed. It has been imperative that an expert in electromagnetic dosimetry be involved in study design, though even today this requirement is often ignored. The RF Safety committee contains expertise in dosimetry that often discovers experimental errors in published results due to misstatements of the amount of exposure that subjects experienced.

Epidemiological studies have the potential to recognize disease trends in populations. However, they can also develop misleading results. Epidemiology looks for health trends among people with similar types of exposures as compared to a similar group of people that does not have the same type of exposure. (This type of study has become difficult to perform with cellular telephones because it is hard to find people who do not use them). The great diversity of the population makes it difficult to know that there is not some other exposure that affects the study group. The RF Safety committee contains expertise in epidemiology to make sense of claims based on epidemiological evidence, and the review of the methods and results can reveal a lesser impact of the study than the author or the press had implied.

Some experimental studies correctly demonstrate biological changes due to exposure to electromagnetic fields. A change in a biological tissue that occurs because of the presence of some form of energy may be an interesting finding, but it does not imply that this change will lead to a public health problem. (An obvious example is contraction of the eye pupil in the presence of bright light, a form of electromagnetic energy). The RF Safety Committee contains expertise in Public Health that helps to determine if there may be a correlation between a laboratory finding and any potential concern for the health of people in our society.

The ARRL RF Safety Committee serves as a resource to the ARRL Board of Directors, providing advice that helps them formulate ARRL policy related to RF safety. The RFSC interacts with the ARRL HQ staff to ensure that RF safety is appropriately addressed in ARRL publications and on the ARRL website. The Amateur Radio community corresponds with the RFSC for help with RF safety-related questions and problems. RFSC members monitor and analyze relevant published research. Its members participate in standards coordinating committees and other expert committees related to RF safety. The RFSC is responsible for writing the RF safety text that is included in ARRL publications. The accuracy of RF safety-related issues in articles submitted to *QST* and *QEX* are confirmed by committee members. The RFSC also participates in developing the RF safety questions for FCC amateur question pools and works with the FCC in developing its environmental regulations. Radio amateurs with questions related to RF safety can contact the RFSC via its liaison, Ed Hare, W1RFI, **w1rfi@arrl.org**. The RFSC maintains a webpage at **www.arrl.org/arrl-rf-safety-committee**.

had the same features: They are transitory, or go away when the EMF exposure is removed, and they have not been associated with any negative health effects.

### 28.3.2 Researching Biological Effects of EMF Exposure

The statistical basis of scientific research that confuses many non-scientists is the inability of science to state unequivocally that EMF is safe. Effects are studied by scientists using statistical inference where the "null hypothesis" assumes there is no effect and then tries to disprove this assumption by proving an "alternative hypothesis" that there is an effect. The alternative hypothesis can never be entirely disproved because a scientist cannot examine every possible case, so scientists only end up with a *probability* that the alternative hypothesis is *not* true. Thus, to be entirely truthful, a scientist can never say that something was proven; with respect to low-level EMF exposure, no scientist can guarantee that it is absolutely safe. At best, science can only state that there is a very low probability that it is unsafe. While scientists accept this truism, many members of the general public who are suspicious of EMF and its effects on humans see this as a reason to continue to be afraid.

There are two types of scientific study that are used to learn about the effects of EMF exposure on mammalian biology: laboratory and epidemiological.

#### LABORATORY STUDY

Scientists conduct laboratory research using animals to learn about biological mecha-

## Preliminary Epidemiology

Just about every week you can pick up the newspaper and see a screaming banner headline such as: "Scientists Discover Link Between Radio Waves and Disease." So why are you still operating your ham radio? You've experienced the inconsistency in epidemiological study of diseases. This is something that every radio amateur should understand in order to know how to interpret the real meaning of the science behind the headlines and to help assuage the fears that these stories elicit in others.

Just knowing that someone who uses a radio gets a disease, such as cancer, doesn't tell us anything about the cause-and-effect of that disease. People came down with cancer, and most other diseases, long before radio existed. What epidemiologists try to identify is a group of people who all have a common exposure to something and all suffer from a particular disease in higher proportion than would be expected if they were not exposed. This technique has been highly effective in helping health officials notice excesses of disease due to things such as poisoning of water supplies by local industry and even massive exposures such as smoking. However, epidemiology rarely proves that an exposure causes a disease; rather it provides the evidence that leads to further study.

While the strength of epidemiology is that it helps scientists notice anomalies in entire populations, its weakness is that it is non-specific. An initial epidemiological study examines only two things: suspected exposures and rates of diseases. These studies are relatively simple and inexpensive to perform and may point to an apparent association that then bears further study. For instance, in one study of the causes of death of a selection of Amateur Radio operators, an excess of leukemia was suggested. The percentage of ham radio operators who died of leukemia in that study was higher than expected based on the percentage of the rest of the population that died of leukemia. By itself, this has little meaning and should not be a cause for concern, since the study did not consider anything else about the sample population except that they had ham licenses. Many other questions arise: Were the study subjects exposed to any unusual chemicals? Did any of the study subjects have a family history of leukemia? Did the licensed amateurs even operate radios, what kind and how often? To an epidemiologist, this result might provide enough impetus to raise the funds to gather more specific information about each subject and perform a more complete study that strengthens the apparent associations. However, a slight excess of disease in a preliminary study rarely leads to further study. Commonly, an epidemiologist does not consider a preliminary study to be worth pursuing unless the ratio of excess disease, also called the risk ratio, is 4:1 or greater. Unfortunately, most news reporters are not epidemiologists and do not understand this distinction. Rather, a slight excess of disease in a preliminary study can lead to banner headlines that raise fear in the society, causing unreasonable resistance to things like cell phones and ham radios.

Headlines that blow the results of preliminary epidemiological studies out of proportion are rarely followed by retractions that are as visible if the study is followed up by one that is more complete and shows no association with disease. In the case of the aforementioned epidemiological study of hams' licensing and death records, overblown publicity about the results has led to the urban legend that ham radio operators are likely to come down with leukemia. Not only is this an unfounded conclusion due to the preliminary nature of the original study, but a similar study was recently performed by the National Cancer Institute using a far larger number of subjects and no significant excess of any disease was found. Hams should be able to recognize when sensationalistic headlines are based on inconclusive science and should be prepared to explain to their families, friends and neighbors just how inconclusive such results are.

nisms by which EMF may affect mammals. The main advantage of laboratory studies on the biological effects of EMF is that the exposures can be controlled very accurately.

Some major disadvantages of laboratory study also exist. EMF exposure may not affect the species of animals used in the investigations the same way that humans may respond. A common example of this misdirection occurred with eye research. Rabbits had been used for many years to determine that exposure of the eyes to high levels of EMF could cause cataracts. The extrapolation of these results to humans led to the fear that use of radio would harm one's vision. However, the rabbit's eye is on the surface of its skull while the human eye is buried deep within the bony orbit in the skull. Thus, the human eye receives much less exposure from EMF and is less likely to be damaged by the same exposures that had been used in the laboratory experiments on rabbits.

Some biological processes that affect tissue can take many years to occur and laboratory experiments on animals tend to be of shorter duration, in part because the life spans of most animals are much shorter than that of humans. For instance, a typical laboratory rat can be studied at most for two years, during which it progresses from youth to old age with all of the attendant physiological changes that come from normal aging. A disease process that takes multiple exposures over many years to occur is unlikely to be seen in a laboratory study with small animals.

#### EPIDEMIOLOGICAL RESEARCH

Epidemiologists look at the health patterns of large groups of people using statistical methods. In contrast to laboratory research, epidemiological research has very poor control of its subjects' exposures to EMF but it has the advantages of being able to analyze the effects of a lifetime of exposure and of being able to average out variations among large populations of subjects. By their basic design, epidemiological studies do not demonstrate cause and effect, nor do they postulate mechanisms of disease. Instead, epidemiologists look for associations between an environmental factor and an observed pattern of illness. Apparent associations are often seen in small preliminary studies that later are shown to have been incorrect. At best, such results are used to motivate more detailed epidemiological studies and laboratory studies that narrow down the search for cause-and-effect.

Some preliminary studies have suggested a weak association between exposure to EMF at home or at work and various malignant conditions including leukemia and brain cancer. A larger number of equally well-designed and performed studies, however, have found no association. Risk ratios as high as 2 have been observed in some studies. This means that the number of observed cases of disease in the test group is up to 2 times the "expected" number in the population. Epidemiologists generally regard a risk ratio of 4 or greater to be indicative of a strong association between the cause and effect under study. For example, men who smoke one pack of cigarettes per day increase their risk for lung cancer tenfold compared to nonsmokers and two packs per day increases the risk to more than 25 times the nonsmokers' risk.

Epidemiological research by itself is rarely conclusive, however. Epidemiology only identifies health patterns in groups — it does not ordinarily determine their cause. There are often confounding factors. Most of us are exposed to many different environmental hazards that may affect our health in various ways. Moreover, not all studies of persons likely to be exposed to high levels of EMF have yielded the same results (see sidebar on preliminary epidemiological studies).

### 28.3.3 Safe Exposure Levels

How much EMF energy is safe? Scientists and regulators have devoted a great deal of effort to deciding upon safe RF-exposure limits.

This is a very complex problem, involving difficult public health and economic considerations. The recommended safe levels have been revised downward several times over the years — and not all scientific bodies agree on this question even today. The latest Institute of Electrical and Electronics Engineers (IEEE) C95.1 standard for recommended radio frequency exposure limits was published in 2006, updating one that had previously been published in 1991 and adopted by the American National Standards Institute (ANSI) in 1992. In the new standard changes were made to better reflect the current research, especially related to the safety of cellular telephones. At

## Where Do RF Safety Standards Come From?

So much of the way we deal with RF Safety is based on "Safety Standards." The FCC environmental exposure regulations that every ham must follow are largely restatements of the conclusions reached by some of the major safety standards. How are these standards developed and why should we trust them?

The preeminent RF safety standard in the world was developed by the Institute of Electrical and Electronics Engineers (IEEE). The most recent edition is entitled *C95.1 -2005: IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz.* The IEEE C95.1 Standard has a long history. The first C95.1 RF safety standard was released in 1966, was less than 2 pages long and listed no references. It essentially said that for frequencies between 10 MHz and 100 GHz people should not be exposed to a power density greater than 10 mW/cm$^2$. The C95.1 standard was revised in 1974, 1982, 1991 and 2005. The latest (2005) edition of the standard was published in 2006, is 250 pages long and has 1143 references to the scientific literature. Most of the editions of the IEEE C95.1 standard were adopted by the American National Standards Institute (ANSI) a year or two after they were published by IEEE. The 2005 edition was adopted by ANSI in 2006.

The committee at IEEE that developed the latest revision to C95.1 is called International Committee on Electromagnetic Safety Technical Committee 95 Subcommittee 4 and had a large base of participants. The subcommittee was co-chaired by C-K Chou, Ph.D., of Motorola Laboratories, and John D'Andrea, PhD, of the U.S. Naval Health Research Center. The committee had 132 members, 42% of whom were from 23 countries outside the United States. The members of the committee represented academia (27%), government (34%), industry (17%), consultants (20%) and the general public (2%).

Early editions of C95.1 were based on the concept that heat generated in the body should be limited to prevent damage to tissue. Over time the standard evolved to protect against *all known adverse biological effects* regardless of the amount of heat generated. The 2005 revision was based on the principles that the standard should protect human health yet still be practical to implement, its conclusions should be based solely on scientific evidence and wherever scientifically defensible it should be harmonized with other international RF safety standards. It based its conclusions on 50 years of scientific study. From over 2500 studies on EMF performed during that time, 1300 were selected for their relevance to the health effects of RF exposure. The science in these studies was evaluated for its quality and methodology and 1143 studies were referenced in producing the latest standard.

Other major standards bodies have published similar standards. The National Council for Radiation Protection and Measurement (NCRP) published its safety standard entitled, *Report No. 86: Biological Effects and Exposure Criteria for Radiofrequency Electromagnetic Fields* in 1986. The International Commission on Non-Ionizing Radiation Protection (ICNIRP) published its safety standard entitled *Guidelines for Limiting Exposure to Time-Varying Electric, Magnetic, and Electromagnetic Fields (Up to 300 GHz)* in 1998.

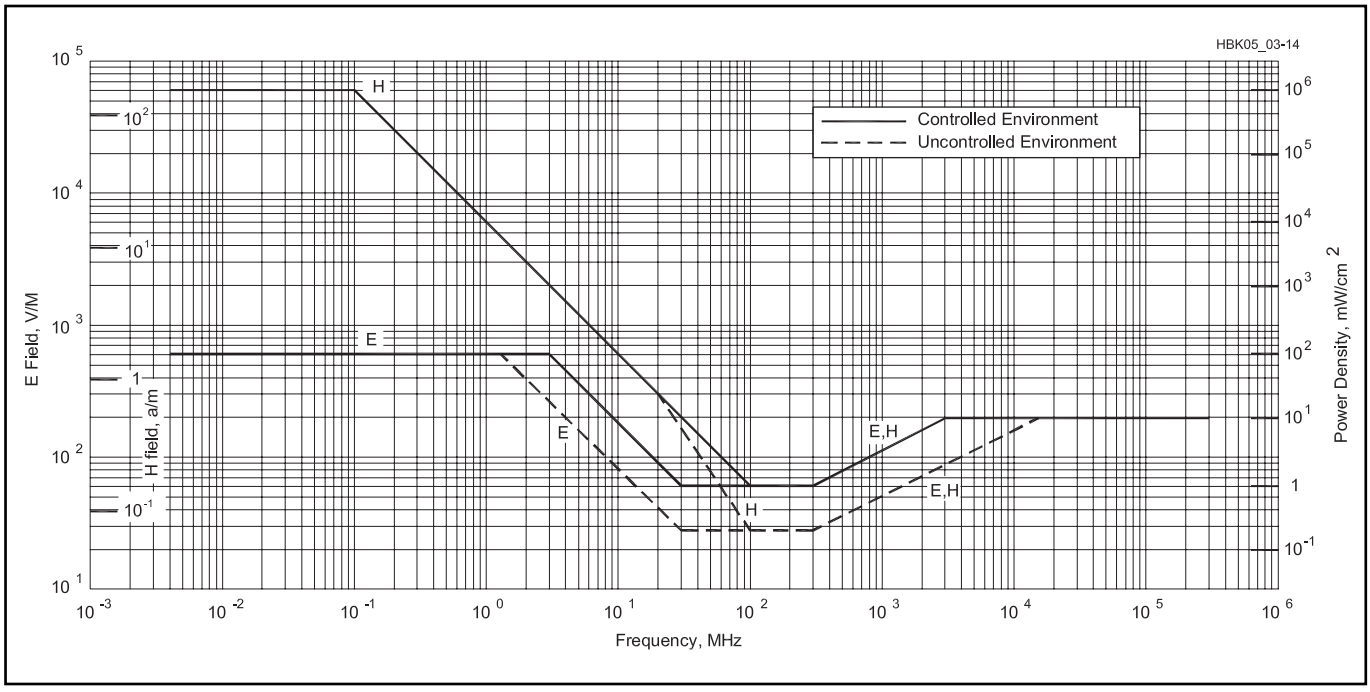

**Figure 28.22 — 1991 RF protection guidelines for body exposure of humans. It is known officially as the "IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz."**

## FCC RF Exposure Regulations

FCC regulations control the amount of RF exposure that can result from your station's operation (§§97.13, 97.503, 1.1307 (b)(c)(d), 1.1310, 2.1091 and 2.1093). The regulations set limits on the maximum permissible exposure (MPE) allowed from operation of transmitters in all radio services. They also require that certain types of stations be evaluated to determine if they are in compliance with the MPEs specified in the rules. The FCC has also required that questions on RF environmental safety practices be added to Technician and General license examinations.

**Table A**
**(From §1.1310) Limits for Maximum Permissible Exposure (MPE)**

**(A) Limits for Occupational/Controlled Exposure**

| *Frequency Range (MHz)* | *Electric Field Strength (V/m)* | *Magnetic Field Strength (A/m)* | *Power Density ($mW/cm^2$)* | *Averaging Time (minutes)* |
|---|---|---|---|---|
| 0.3-3.0 | 614 | 1.63 | (100)* | 6 |
| 3.0-30 | 1842/f | 4.89/f | ($900/f^2$)* | 6 |
| 30-300 | 61.4 | 0.163 | 1.0 | 6 |
| 300-1500 | — | — | f/300 | 6 |
| 1500-100,000 | — | — | 5 | 6 |

f = frequency in MHz
* = Plane-wave equivalent power density (see Notes 1 and 2).

**(B) Limits for General Population/Uncontrolled Exposure**

| *Frequency Range (MHz)* | *Electric Field Strength (V/m)* | *Magnetic Field Strength (A/m)* | *Power Density ($mW/cm^2$)* | *Averaging Time (minutes)* |
|---|---|---|---|---|
| 0.3-1.34 | 614 | 1.63 | (100)* | 30 |
| 1.34-30 | 824/f | 2.19/f | ($180/f^2$)* | 30 |
| 30-300 | 27.5 | 0.073 | 0.2 | 30 |
| 300-1500 | — | — | f/1500 | 30 |
| 1500-100,000 | — | — | 1.0 | 30 |

f = frequency in MHz
* = Plane-wave equivalent power density (see Notes 1 and 2).

Note 1: This means the equivalent far-field strength that would have the E or H-field component calculated or measured. It does not apply well in the near field of an antenna. The equivalent far-field power density can be found in the near or far field regions from the relationships: $P_d = |E_{total}|^2 / 3770$ mW/cm$^2$ or from $P_d = |H_{total}|^2 \times 37.7$ mW/cm$^2$.

Note 2: $|E_{total}|^2 = |E_x|^2 + |E_y|^2 + |E_z|^2$, and $|H_{total}|^2 = |H_x|^2 + |H_y|^2 + |H_z|^2$

### THE RULES

### Maximum Permissible Exposure (MPE)

All radio stations regulated by the FCC must comply with the requirements for MPEs, even QRP stations running only a few watts or less. The MPEs vary with frequency, as shown in **Table A**. MPE limits are specified in maximum electric and magnetic fields for frequencies below 30 MHz, in power density for frequencies above 300 MHz and all three ways for frequencies from 30 to 300 MHz. For compliance purposes, all of these limits must be considered *separately*. If any one is exceeded, the station is not in compliance. In effect, this means that both electric and magnetic field must be determined below 300 MHz but at higher frequencies determining either the electric or magnetic field is normally sufficient.

The regulations control human exposure to RF fields, not the strength of RF fields in any space. There is no limit to how strong a field can be as long as no one is being exposed to it, although FCC regulations require that amateurs use the minimum necessary power at all times (§97.311 [a]).

### Environments

The FCC has defined two tiers of exposure limits — *occupational/controlled limits* and *general population/uncontrolled limits*. Occupational/controlled limits apply when people are exposed as a condition of their employment and when they are aware of that exposure and can take steps to minimize it, if appropriate. General population/uncontrolled limits apply to exposure of the general public or people who are not normally aware of the exposure or cannot exercise control over it. The limits for general population/uncontrolled exposure are more stringent than the limits for occupational/controlled exposure. Specific definitions of the exposure categories can be found in Section 1.1310 of the FCC rules.

Although occupational/controlled limits are usually applicable in a workplace environment, the FCC has determined that they generally apply to amateur operators and members of their immediate households. In most cases, occupational/controlled limits can be applied to your home and property to which you can control physical access. The general population/uncontrolled limits are intended for areas that are accessible by the general public, such as your neighbors' properties.

The MPE levels are based on average exposure. An averaging time of 6 minutes is used for occupational/controlled exposure; an averaging period of 30 minutes is used for general population/uncontrolled exposure.

### Station Evaluations

On May 3, 2021, changes to the FCC rules on RF exposure became effective

some frequencies the new standard determined that higher levels of exposure than previously thought are safe (see sidebar, "Where Do RF Safety Standards Come From?").

The IEEE C95.1 standard recommends frequency-dependent and time-dependent maximum permissible exposure levels. Unlike earlier versions of the standard, the 1991 and 2006 standards set different RF exposure limits in *controlled environments* (where energy levels can be accurately determined and everyone on the premises is aware of the presence of EM fields) and in *uncontrolled environments* (where energy levels are not known or where people may not be aware of the presence of EM fields). FCC regulations adopted these concepts to include controlled/occupational and uncontrolled/general population exposure limits.

The graph in **Figure 28.22** depicts the 1991 IEEE standard (which is still used as the basis of FCC regulation). It is necessarily a complex graph, because the standards differ not only for controlled and uncontrolled environments but also for electric (E) fields and magnetic (H) fields. Basically, the lowest E-field exposure limits occur at frequencies between 30 and 300 MHz. The lowest H-field exposure levels occur at 100-300 MHz. The ANSI standard sets the maximum E-field limits between 30 and 300 MHz at a power density of 1 mW/cm$^2$ (61.4 V/m) in controlled environments — but at one-fifth that level (0.2 mW/cm$^2$ or 27.5 V/m) in uncontrolled environments. The H-field limit drops to 1 mW/cm$^2$ (0.163 A/m) at 100-300 MHz in controlled environments

(**docs.fcc.gov/public/attachments/FCC-19-126A1.pdf**). The new rules change the ways that transmitter operators can determine whether they are exempt from the requirement to perform a routine RF exposure calculation for their stations. The FCC reminds us that the exposure limits have not changed. Whether station operators are required to perform complete evaluations or are exempt, they are still required to comply with all FCC exposure thresholds. There is no two-year compliance period for this requirement, it was always that way.

Under the old rules, the FCC had specific criteria for amateur stations to determine whether they needed to do an evaluation. Regular evaluations were not required under conditions that were either based on frequency and power level, or for specific types of transmitters such as PTT-operated mobile and portable devices and most amateur repeaters. The old criteria were not always valid, so the FCC changed the criteria to a set of formulas that apply to all radio services and include distance from the antenna to the nearest person, called the *point of exposure*. (If a person is not present, there is no exposure.)

Start by determining how far the point of exposure is from the antenna. If it is farther from the antenna than the *minimum exemption distance* of 0.16 wavelengths ($\lambda/2\pi$) as shown in Table B, all you need to do is use the new formulas in Table C to calculate the *maximum exempt effective radiated power* (ERP) based on the operating frequency in megahertz and distance in meters to the point of exposure. If the station's ERP is lower than that calculated value, the operator is exempt from the need to calculate whether exposure is below the limits.

The new exemption formulas in Table C intentionally overestimate exposure so there will be no chance of overexposure from an exempt station. They do not take into account averaging periods with the transmission duty cycle or the modulation duty factor. They assume that the gain of an antenna applies in all directions, which is rarely the case.

If the point of exposure is closer than the minimum exemption distance or if the station ERP is greater than the maximum exempt ERP, a more detailed RF exposure evaluation is required. In most cases, it is easy to do an RF exposure evaluation by using online calculators or antenna modeling. Although amateurs can make measurements of field strength from their stations if they have appropriate equipment, measurements are not required. The FCC also does not require amateurs to submit any paperwork about the results of their evaluations, although ARRL does recommend that amateurs keep a copy of their evaluations in their station records.

Most stations that are not eligible for an exemption will find that they are under the exposure thresholds when a complete RF exposure evaluation is performed. Stations that use indoor antennas or high-duty cycle digital modes may need to make adjustments to be in compliance. Even if the station is found to exceed the FCC exposure thresholds after performing a complete evaluation, there are several mitigations that can be taken to keep operating. For example, hams can adjust their operating frequency, mode, or power. They can also adjust their operating habits or control the direction of the antenna.

If an amateur has previously performed a station evaluation, that evaluation will not need to be repeated. For station operation that was categorically exempt under the old rules, amateurs will have until May 3, 2023 to perform the needed evaluation. If an amateur makes a change to station operation that could affect RF exposure, such as increasing power levels or changing an antenna, that amateur will have to do an evaluation before placing that station change into operation.

This is only an overview of RF exposure regulations. Information on the FCC formulas to determine exemption, links to web pages that perform RF exposure calculations, and answers to most common questions about RF exposure can be found in the ARRL RF-Exposure web page at **arrl.org/rf-exposure**, including a free downloadable edition of the ARRL book, *RF Exposure and You*.

**Table B**
**Minimum Exemption Distances ($\lambda/2\pi$)**

| *Band (MHz)* | *Distance* | *Band (MHz)* | *Distance* |
|---|---|---|---|
| 1.8 | 87.0 ft | 24.9 | 6.3 ft |
| 3.6 | 43.5 ft | 28.2 | 5.6 ft |
| 3.9 | 40.2 ft | 50.1 | 3.1 ft |
| 7.1 | 22.1 ft | 146 | 1.1 ft |
| 10.1 | 15.5 ft | 223 | 8.4 in |
| 14.1 | 11.1 ft | 440 | 4.3 in |
| 18.1 | 8.7 ft | 902 | 2.1 in |
| 21.2 | 7.4 ft | 1296 | 1.5 in |

**Table C**
**Maximum Exempt ERP**

| | *Frequency (MHz)* | *Maximum ERP (Watts)* |
|---|---|---|
| VLF | 0.3 – 1.34 | $1920 \times R^2$ |
| HF | 1.34 – 30 | $3450 \times R^2 / f^2$ |
| VHF | 30 – 300 | $3.83 \times R^2$ |
| UHF | 300 – 1500 | $0.0128 \times R^2 \times f$ |
| MW | 1500 – 100,000 | $19.2 \times R^2$ |

Note: R is distance in meters and f is frequency in MHz

*Example Calculations:*

On 14.1 MHz at 10 meters from the antenna, the maximum exempt ERP is
$3450 \times 10^2 / 14.1^2 = 1735$ W

On 28.2 MHz at 10 meters from the antenna, the maximum exempt ERP is
$3450 \times 10^2 / 28.2^2 = 433$ W

On 50.1 MHz at 5 meters from the antenna, the maximum exempt ERP is
$3.83 \times 5^2 = 96$ W

On 146 MHz at 0.5 meters from the antenna, the maximum exempt ERP is
$3.83 \times 0.5^2 = 0.96$ W

and 0.2 mW/cm$^2$ (0.0728 A/m) in uncontrolled environments. Higher power densities are permitted at frequencies below 30 MHz (below 100 MHz for H fields) and above 300 MHz, based on the concept that the body will not be resonant at those frequencies and will therefore absorb less energy.

In general, the ANSI/IEEE standard requires averaging the power level over time periods ranging from 6 to 30 minutes for power-density calculations, depending on the frequency and other variables. The ANSI/IEEE exposure limits for uncontrolled environments are lower than those for controlled environments, but to compensate for that the standard allows exposure levels in those environments to be averaged over much longer time periods (generally 30 minutes). This long averaging time means that an intermittent RF source (such as an Amateur Radio transmitter) will result in a much lower exposure than a continuous-duty station, with all other parameter being equal. Time averaging is based on the concept that the human body can withstand a greater rate of body heating (and thus, a higher level of RF energy) for a short time.

Another national body in the United States, the National Council for Radiation Protection and Measurement (NCRP), also has adopted recommended exposure guidelines. NCRP urges a limit of 0.2 mW/cm$^2$ for nonoccupational exposure in the 30- 300 MHz range. The NCRP guideline differs from IEEE in that it takes into account the effects of modulation on an RF carrier.

The FCC MPE regulations are based on a combination of the 1992 ANSI/IEEE standard and 1986 NCRP recommendations. The MPE limits under the regulations are slightly different than the ANSI/IEEE limits and do not reflect all the assumptions and exclusions of the ANSI/IEEE standard.

### 28.3.4 Cardiac Pacemakers and RF Safety

It is a widely held belief that cardiac pacemakers may be adversely affected in their function by exposure to electromagnetic fields. Amateurs with pacemakers may ask whether their operating might endanger themselves or visitors to their shacks who have a pacemaker. Because of this, and similar concerns regarding other sources of EM fields, pacemaker manufacturers apply design methods that for the most part shield the pacemaker circuitry from even relatively high EM field strengths.

It is recommended that any amateur who has a pacemaker, or is being considered for one, discuss this matter with his or her physician. The physician will probably put the amateur into contact with the technical representative of the pacemaker manufacturer. These representatives are generally excellent resources, and may have data from laboratory or "in the field" studies with specific model pacemakers.

One study examined the function of a modern (dual chamber) pacemaker in and around an Amateur Radio station. The pacemaker generator has circuits that receive and process electrical signals produced by the heart, and also generate electrical signals that stimulate (pace) the heart. In one series of experiments, the pacemaker was connected to a heart simulator. The system was placed on top of the cabinet of a 1-kW HF linear amplifier during SSB and CW operation. In another test, the system was placed in close proximity to several 1 to 5-W 2-meter hand-held transceivers. The test pacemaker was connected to the heart simulator in a third test, and then placed on the ground 9 meters below and 5 meters in front of a three-element Yagi HF antenna. No interference with pacemaker function was observed in these experiments.

Although the possibility of interference cannot be entirely ruled out by these few observations, these tests represent more severe exposure to EM fields than would ordinarily be encountered by an amateur — with an average amount of common sense. Of course prudence dictates that amateurs with pacemakers, who use handheld VHF transceivers, keep the antenna as far as possible from the site of the implanted pacemaker generator. They also should use the lowest transmitter output required for adequate communication. For high power HF transmission, the antenna should be as far as possible from the operating position, and all equipment should be properly grounded.

### 28.3.5 Low-Frequency Fields

There has been considerable laboratory research about the biological effects of power line EMF. For example, some separate studies have indicated that even fairly low levels of EMF exposure might alter the human body's circadian rhythms, affect the manner in which T lymphocytes function in the immune system and alter the nature of the electrical and chemical signals communicated through the cell membrane and between cells, among other things. Although these studies are intriguing, they do not demonstrate any effect of these low-level fields on the overall organism.

Much of this research has focused on low-frequency magnetic fields, or on RF fields that are keyed, pulsed or modulated at a low audio frequency (often below 100 Hz). Several studies suggested that humans and animals could adapt to the presence of a steady RF carrier more readily than to an intermittent, keyed or modulated energy source.

The results of studies in this area, plus speculations concerning the effect of various types of modulation, were and have remained somewhat controversial. None of the research to date has demonstrated that low-level EMF causes adverse health effects.

Given the fact that there is a great deal of ongoing research to examine the health consequences of exposure to EMF, the American Physical Society (a national group of highly respected scientists) issued a statement in May 1995 based on its review of available data pertaining to the possible connections of cancer to 60-Hz EMF exposure. Their report is exhaustive and should be reviewed by anyone with a serious interest in the field. Among its general conclusions are the following:

1. The scientific literature and the reports of reviews by other panels show no consistent, significant link between cancer and power line fields.

2. No plausible biophysical mechanisms for the systematic initiation or promotion of cancer by these extremely weak 60-Hz fields have been identified.

3. While it is impossible to prove that no deleterious health effects occur from exposure to any environmental factor, it is necessary to demonstrate a consistent, significant, and causal relationship before one can conclude that such effects do occur.

In a report dated October 31, 1996, a committee of the National Research Council of the National Academy of Sciences has concluded that no clear, convincing evidence exists to show that residential exposures to electric and magnetic fields (EMF) are a threat to human health.

A National Cancer Institute epidemiological study of residential exposure to magnetic fields and acute lymphoblastic leukemia in children was published in the *New England Journal of Medicine* in July 1997. The exhaustive, seven-year study concludes that if there is any link at all, it is far too weak to be of concern.

In 1998, the US National Institute on Environmental Health Sciences organized a working group of experts to summarize the research on power-line EMF. The committee used the classification rules of the International Agency for Research on Cancer (IARC) and performed a meta-analysis to combine all past results as if they had been performed in a single study. The NIEHS working group concluded that the research did not show this type of exposure to be a carcinogen but could not rule out the possibility either. Therefore, they defined power-line EMF to be a Class 2b carcinogen under the IARC classification. The definition, as stated by the IARC is: "Group 2B: The agent is possibly carcinogenic to humans. There is

**Table 28.4**
**Typical 60-Hz Magnetic Fields Near Amateur Radio Equipment and AC-Powered Household Appliances**

Values are in milligauss.

| *Item* | *Field* | *Distance* |
|---|---|---|
| Electric blanket | 30-90 | Surface |
| Microwave oven | 10-100 | Surface |
| | 1-10 | 12 in. |
| IBM personal computer | 5-10 | Atop monitor |
| | 0-1 | 15 in. from screen |
| Electric drill | 500-2000 | At handle |
| Hair dryer | 200-2000 | At handle |
| HF transceiver | 10-100 | Atop cabinet |
| | 1-5 | 15 in. from front |
| 1-kW RF amplifier | 80-1000 | Atop cabinet |
| | 1-25 | 15 in. from front |

(Source: measurements made by members of the ARRL RF Safety Committee)

limited pidemiological evidence plus limited or inadequate animal evidence." Other IARC Class 2b carcinogens include automobile exhaust, chloroform, coffee, ceramic and glass fibers, gasoline and pickled vegetables.

Readers may want to follow this topic as further studies are reported. Amateurs should be aware that exposure to RF and ELF (60 Hz) electromagnetic fields at all power levels and frequencies has not been fully studied under all circumstances. "Prudent avoidance" of any avoidable EMF is always a good idea. Prudent avoidance doesn't mean that amateurs should be fearful of using their equipment. Most amateur operations are well within the MPE limits. If any risk does exist, it will almost surely fall well down on the list of causes that may be harmful to your health (on the other end of the list from your automobile). It does mean, however, that hams should be aware of the potential for exposure from their stations, and take whatever reasonable steps they can take to minimize their own exposure and the exposure of those around them.

Although the FCC doesn't regulate 60-Hz fields, some recent concern about EMF has focused on 60 Hz. Amateur Radio equipment can be a significant source of 60 Hz fields, although there are many other sources of this kind of energy in the typical home. Magnetic fields can be measured relatively accurately with inexpensive 60-Hz meters that are made by several manufacturers.

**Table 28.4** shows typical magnetic field intensities of Amateur Radio equipment and various household items.

**Table 28.5**
**Typical RF Field Strengths Near Amateur Radio Antennas**
A sampling of values as measured by the Federal Communications Commission and Environmental Protection Agency, 1990

| *Antenna Type* | *Freq (MHz)* | *Power (W)* | *E Field (V/m)* | *Location* |
|---|---|---|---|---|
| Dipole in attic | 14.15 | 100 | 7-100 | In home |
| Discone in attic | 146.5 | 250 | 10-27 | In home |
| Half sloper | 21.5 | 1000 | 50 | 1 m from base |
| Dipole at 7-13 ft | 7.14 | 120 | 8-150 | 1-2 m from earth |
| Vertical | 3.8 | 800 | 180 | 0.5 m from base |
| 5-element Yagi at 60 ft | 21.2 | 1000 | 10-20 | In shack |
| | | | 14 | 12 m from base |

| | | | 15-30 | In vehicle |
| | | | 90 | Rear seat |
| 5-element Yagi at 20 ft | 50.1 | 500 | 37-50 | 10 m antenna |

**Table 28.6**
**RF Awareness Guidelines**

*These guidelines were developed by the ARRL RF Safety Committee, based on the FCC/EPA measurements of Table 28.4 and other data.*

- Although antennas on towers (well away from people) pose no exposure problem, make certain that the RF radiation is confined to the antennas' radiating elements themselves. Provide a single, good station ground (earth), and eliminate radiation from transmission lines. Use good coaxial cable or other feed line properly. Avoid serious imbalance in your antenna system and feed line. For high-powered installations, avoid end-fed antennas that come directly into the transmitter area near the operator.
- No person should ever be near any transmitting antenna while it is in use. This is especially true for mobile or ground-mounted vertical antennas. Avoid transmitting with more than 25 W in a VHF mobile installation unless it is possible to first measure the RF fields inside the vehicle. At the 1-kW level, both HF and VHF directional antennas should be at least 35 ft above inhabited areas. Avoid using indoor and attic-mounted antennas if at all possible. If open-wire feeders are used, ensure that it is not possible for people (or animals) to come into accidental contact with the feed line.
- Don't operate high-power amplifiers with the covers removed, especially at VHF/UHF.
- In the UHF/SHF region, never look into the open end of an activated length of waveguide or microwave feed-horn antenna or point it toward anyone. (If you do, you may be exposing your eyes to more than the maximum permissible exposure level of RF radiation.) Never point a high-gain, narrow-bandwidth antenna (a paraboloid, for instance) toward people. Use caution in aiming an EME (moonbounce) array toward the horizon; EME arrays may deliver an effective radiated power of 250,000 W or more.
- With hand-held transceivers, keep the antenna away from your head and use the lowest power possible to maintain communications. Use a separate microphone and hold the rig as far away from you as possible. This will reduce your exposure to the RF energy.
- Don't work on antennas that have RF power applied.
- Don't stand or sit close to a power supply or linear amplifier when the ac power is turned on. Stay at least 24 inches away from power transformers, electrical fans and other sources of high-level 60-Hz magnetic fields.

## 28.3.6 Determining RF Power Density

Unfortunately, determining the power density of the RF fields generated by an amateur station is not as simple as measuring low-frequency magnetic fields. Although sophisticated instruments can be used to measure RF power densities quite accurately, they are costly and require frequent recalibration. Most amateurs don't have access to such equipment, and the inexpensive field-strength meters that we do have are not suitable for measuring RF power density.

**Table 28.5** shows a sampling of measurements made at Amateur Radio stations by the Federal Communications Commission and the Environmental Protection Agency in 1990. As this table indicates, a good antenna well removed from inhabited areas poses no hazard under any of the ANSI/IEEE guidelines. However, the FCC/EPA survey also indicates that amateurs must be careful about using indoor or attic-mounted antennas, mobile antennas, low directional arrays or any other antenna that is close to inhabited areas, especially when moderate to high power is used.

Ideally, before using any antenna that is in close proximity to an inhabited area, you should measure the RF power density. If that is not feasible, the next best option is make the installation as safe as possible by observing the safety suggestions listed in **Table 28.6**.

It also is possible, of course, to calculate the probable power density near an antenna using simple equations. Such calculations have many pitfalls. For one, most of the situations where the power density would be high enough to be of concern are in the near field. In the near field, ground interactions and other variables produce power densities that cannot be determined by simple arithmetic. In the far field, conditions become easier to predict with simple calculations. (See the February 2013 *QST* article "Q and the

Energy Stored Around Antennas" by Kai Siwiak, KE4PT and the **Antennas** chapter of this book for more information about stored energy density near antennas.)

The boundary between the near field and the far field depends on the wavelength of the transmitted signal and the physical size and configuration of the antenna. The boundary between the near field and the far field of an antenna can be as much as several wavelengths from the antenna.

Computer antenna-modeling programs are another approach you can use. *MININEC* or other codes derived from *NEC* (Numerical Electromagnetics Code) are suitable for estimating RF magnetic and electric fields around amateur antenna systems.

These models have limitations. Ground interactions must be considered in estimating near-field power densities, and the "correct ground" must be modeled. Computer modeling is generally not sophisticated enough to predict "hot spots" in the near field — places where the field intensity may be far higher than would be expected, due to reflections from nearby objects. In addition, "nearby objects" often change or vary with weather or the season, therefore the model so laboriously crafted may not be representative of the actual situation, by the time it is running on the computer.

Intensely elevated but localized fields often can be detected by professional measuring instruments. These "hot spots" are often found near wiring in the shack, and metal objects such as antenna masts or equipment cabinets. But even with the best instrumentation, these measurements also may be misleading in the near field. One need not make precise measurements or model the exact antenna system, however, to develop some idea of the relative fields around an antenna. Computer modeling using close approximations of the geometry and power input of the antenna will generally suffice. Those who are familiar with *MININEC* can estimate their power densities by computer modeling, and those who have access to professional power-density meters can make useful measurements.

While our primary concern is ordinarily the intensity of the signal radiated by an antenna, we also should remember that there are other potential energy sources to be considered. You also can be exposed to excessive RF fields directly from a power amplifier if it is operated without proper shielding. Transmission lines also may radiate a significant amount of energy under some conditions. Poor microwave waveguide joints or improperly assembled connectors are another source of incidental exposure.

### 28.3.7 Further RF Exposure Suggestions

Potential exposure situations should be taken seriously. Based on the FCC/EPA measurements and other data, the "RF awareness" guidelines of Table 28.6 were developed by the ARRL RF Safety Committee. A longer version of these guidelines, along with a complete list of references, appeared in a *QST* article by Ivan Shulman, MD, WC2S ("Is Amateur Radio Hazardous to Our Health?" *QST*, Oct 1989, pp 31-34).

In addition, the ARRL has published a book, *RF Exposure and You* that helps hams comply with the FCC's RF-exposure regulations. The ARRL also maintains an RF-exposure news page on its website. See **www.arrl.org/rf-exposure**. This site contains reprints of selected *QST* articles on RF exposure and links to the FCC and other useful sites.

#### SUMMARY

The ideas presented in this chapter are intended to reinforce the concept that ham radio, like many other activities in modern life, does have certain risks. But by understanding the hazards and how to deal effectively with them, the risk can be minimized. Common-sense measures can go a long way to help us prevent accidents. Traditionally, amateurs are inventors, and experimenting is a major part of our nature. But reckless chance-taking is never wise, especially when our health and well-being is involved. A healthy attitude toward doing things the right way will help us meet our goals and expectations.

## MFJ-259D Analyzer, $329.95

**World's** best selling antenna analyzer covers 280 KHz to 230 MHz, LCD, SWR and impedance or SWR bargraph, analog meters, signal generator, freq counter.

## MFJ-269D Analyzer, $429.95

**Upgraded** MFJ-269D has all features of MFJ-259D plus 415-470 MHz, 12-bit A/D converter, characteristic impedance 0-600 Ohms, coax calculator, parallel equivalent R/X.

## MFJ-225 VNA Analyzer, $349.95

**1.8-170 MHz.** Plots *SWR, Impedance, Resistance, Reactance, Phase Angle, Complex Return Loss, Smith Chart.* Open-Short-Load calibration. Memories download to PC via USB.

## MFJ-949E Tuner $229.95

**More** hams use MFJ-949E tuners than all others in the world! Large 3" cross-needle SWR/Wattmeter, 8 position antenna switch, dummy load, Match any antenna 1.8-30 MHz.

## MFJ-969 Tuner $269.95

**World's** only 6 -160 Meters 300 Watt *AirCore*™ Roller Inductor antenna tuner gives you absolute minimum SWR. 3" cross-needle meter, true peak reading meter, dummy load, 8 pos. antenna switch.

## MFJ-962D Tuner $369.95

**Compact** *roller inductor* antenna tuner handles popular Ameritron AL-811H/811 amps. *AirCore*™ inductor, 3" Cross-Needle meter, 6-position antenna switch, 800W SSB PEP output.

## MFJ-989D Tuner $439.95

**Legal-limit** antenna tuner has *Air-Core*™ inductor, 500pF air variable capacitors, fast-tune crank, high voltage balun, 3" meter, dummy load, ant. switch.

## MFJ-929 AutoTuner $279.95

**Compact** 200 Watt *IntelliTuner*™ tunes any unbalanced antenna *ultra-fast!* 20,000 Virtual Memories, Antenna Switch, Efficient L-network, Matches 6-1600 Ohms from 1.8-30 MHz.

## MFJ-993B AutoTuner $309.95

**Select** 300 Watts (6-1600 Ohms) or 150 Watts (6-3200 Ohms) with the *world's only dual power* automatic tuner. 1.8-30 MHz, 4:1 current balun, LED lighted cross meter, backlit LCD, more!

## MFJ-998 AutoTuner $749.95

**Full** 1500 Watts SSB/CW. Digital and analog SWR/Wattmeter, 12-1600 Ohms from 1.8-30 MHz, built-in antenna switch, auto amp bypass.

## MFJ-1778 G5RV $59.95

**Efficient**, *all band* G5RV antenna is only 102' long, has 32.5' ladder line matching section ending in an SO-239 for feedline. Operate 80-10 Meters with tuner. 1500 Watts.

## MFJ-16XX HF Sticks $17.95

**Rugged**, sleek **6-40M** mobile *HamTenna*™ antennas, **$24.95** each band. 250 Watts, 7' extended, collapse to about 4 feet for storage. Quickly screws into any 3/8-24 female mount for quick band changing. **60-75M, $34.95.**

## MFJ-1836H Cobweb $309.95

**Antenna for restricted spaces:** 6-bands: 20/17/15/12/10/6 Meters. Flat 9x9x½ sq. ft. mounts horizontally on mast. Nearly invisible wire elements, fiberglass spreaders blend in sky. Withstands bad weather.

## MFJ-1786 HiQ Loop $509.95

**10-30 MHz** Super Hi-Q loop, remote control. 36" dia. all welded construction, butterfly tuning capacitor. ABS plastic housing. **MFJ-1788, $579.95.** 7-22 MHz.

## MFJ-260C Dry Load $44.95

**300W** VHF/HF Dry Dummy Load handles full load for 30 seconds. Derating curve to 5 minutes. SWR below 1.1:1 to 30 MHz. 1.5:1 from 30-650 MHz. **MFJ-264, $79.95.** 1.5kW load.

## MFJ-1702C Ant Switch $54.95

**2-position** antenna switch has center ground, auto grounding of unused position, 2.5 kW PEP and works to over 500 MHz. Lightning surge protection. SO-239 Connectors. **MFJ-1704, $119.95.** 4 positions.

## MFJ-915 RFI Isolator $49.95

**Prevents** unwanted RF from traveling on your coax shield into your expensive transceiver. Prevents stray RF that cause painful RF "bites" and eratic operation. Heavy duty weather protected PVC is 2Wx5H inches. 1.5 kW. 1.8-30 MHz.

## MFJ-918 4:1 Balun $44.95

**High**-permeability ferrite beads on high-quality RG-303 *Teflon*® coax. True 1:1 current balun/center insulator. 2" diameter by 6" long. 14 gauge stranded copper wire. Handles 1.5 kW 1.8-30 MHz.

## MFJ-270 Surge Protect $21.95

**Safeguard** your expensive equipment. Shunts to 5000 Amps of peak impulse current harmlessly to ground. SWR less than 1.1:1, less than 0.1 dB loss. Use to 1000 MHz, 400W PEP.

## MFJ-392B Headphones $44.95

**Perfect** for Ham Radio and shortwave listening -- SSB, FM, AM, data and CW. Super lightweight (8 oz.) padded headband and ear cushioned design. Each earphone has own volume control. 3.5mm/1/4" plugs, 9' cord.

## MFJ-4230MV 30A PS $124.95

**World's** most compact 30A switching power supply. V/A meter. 4-16 Volts, adjustable. 5Wx2½Hx6D inches, 3 pounds! Selectable input voltage 120/240 VAC.

## MFJ-4035MV 30A PS $179.95

**19.2 lb.** transformer delivers 35A maximum, 30A continuous. 1-14 VDC out, 110 VAC in. Highly regulated, 1% load regulation. 1 mV Ripple. 5-way binding posts, quick connects.

## MFJ-4245MV 45A PS $159.95

**Switching** power supply. 45A surge/40A continuous. 9-15 VDC out. 85-260 VAC in. Low ripple, highly regulated. 5-way posts, cig lighter, quick connects. 5 lbs., 7½Wx4¾Hx9D".

## MFJ-4275MV 75A PS $294.95

**Switching** power supply. 75A max/70A cont. Great for ALS-500M solid state amp. Adjustable 4-16 VDC. Input 110/220 VAC. Battery charger. 10.5 lbs.

## Antenna Window Feedthrough Panels

***Bring your antenna cables into your hamshack without drilling holes through walls!*** Place in window sill, close window. *Real* western cedar 3/4" thick wood naturally resistant to rot, decay and insects, weather edge foam tape included. *Teflon*® SO-239s for HF/VHF/UHF antennas, *ceramic* feed-thrus for balanced line/random wire, ground post. Stainless steel in/out plates.

**MFJ-4602, $89.95**

## MFJ-868B Giant Meter $159.95

**Largest** HF+6M SWR/Wattmeter in the world has 6.5" diagonal scale. 20/200/2000W ranges.

## MFJ-1026 Noise Cancel $249.95

**Wipe** out interference! 60 dB null. SSB/CW/AM/FM. BCB to lower VHF. RF sense T/R switch.

## MFJ-4416C BattBoost $209.95

**Keep** mobile rig operational. Boosts low battery voltage. Up to 25 Amps. 7¾Wx4Hx2⅛".

## MFJ-148BRC Clock $74.95

***Two*** atomic 24/12 hour clocks -- *single time base*. UTC time, 10-minute ID timer. 1.5 inch LCD.

## MFJ-281 Speaker $13.95

**Get** speech fidelity you never knew existed! 3" speaker, 8W, 8 Ohms impedance, 6' cord, 3.5 mm mono.

## MFJ-461 CodeReader $119.95

**Decodes** and displays Morse code on two-line high-contrast LCD. Just hold close to receiver.

## MFJ-557 CodeOsc/Key $54.95

**Practice** sending Morse code. Telegraph key, code oscillator, speaker on heavy non-skid steel base. Volume/tone controls. Use 9V battery.

## MFJ-564 IambicPaddles $119.95

**Deluxe** Iambic paddles. Tension/contact spacing adjustments, steel bearings, precision frame, non-skid feet. Chrome or Black.

## MFJ-108B 24/12 Clock $24.95

**Read** both UTC and local time *simultaneously*. BIG 5/8 inch digits! Solid brushed aluminum frame. 4¼Wx2Hx1D".

## MFJ-1724B Mobile $39.95

**World's** Best Selling 2Meter 440 MHz magnet mount antenna has 3.5" magnet, 19" stainless steel whip, handles 300 Watts, 15 feet coax.

## MFJ-1728B Mobile $39.95

**5/8** wave 2M mobile antenna gives maximum possible gain of any single element antenna. 1/4 Wave 6M. 300W, magnet mount, 12' coax, 53" whip.

## MFJ-1729 Mobile $54.95

**Ham** radio's *most powerful* magnet mount *dual band* 2M/440 mobile. Get whopping GAIN. 300 Watts, 27.5" stainless steel whip, 12' coax.

# hy-gain Antennas and Rotators

## HF Verticals

***Work amazing DX with these extremely low radiation angle omnidirectional antennas. All self supporting, 1500 Watts PEP SSB, low SWR. Heavy duty, slotted, tapered, swaged, aircraft quality aluminum tubing. Stainless steel hardware. Two year limited warranty.***

**AV-680, $619.95. 9 Bands: (6,10,12,15,17,20,30,40, 80 Meters). 26 ft., 18.5 lbs.** *Our most popular vertical now has 75/80 Meters! Lets you work exciting DX with a low 17 degree radiation angle!* Easily mount on decks, roofs, patios. *No ground or radials needed.* Extra wide 2:1 SWR bandwidths. *Each* band tunable. Auto bandswitching, handle 1.5kW, 80 MPH wind survival, low 2.5 sq. ft. wind surface. Aircraft aluminum tubing, stainless steel hardware.

**AV-640, $519.95.** Like AV-680 less 80M**.** 25½', 17½ lbs.

**AV-620, $419.95.** Like AV-640 less 40M. 22½'/10½ lbs.

**AV-14AVQ, $249.95. (10, 15, 20, 40 Meters). 18 ft., 9 lbs.** *Classic* AV-14AVQ uses same trap design as famous Hy-Gain Thunderbird beams. 3 air dielectric Hi-Q traps with oversize coils give superb stability and 1/4 wave resonance on all bands. Automatic bandswitching.

**AV-12AVQ, $189.95. (10, 15, 20 Meters). 13 ft., 9 lbs.** Lowest priced *automatic bandswitching* tri-band vertical! Uses Thunderbird beam design air dielectric traps for extremely hi-Q performance in limited space.

**AV-18VS, $169.95. (10,12,15,17,20,30,40,80M). 18 ft., 4 lbs.** Hy-gain's *lowest priced vertical* gives you 8 bands. Easily tuned to any band by adjusting base loading coil.

***See our website for even more hy-gain vertical antennas!***

## HF Beams

**Hy-gain** beams are *stronger, lighter, have less wind surface and last years longer.* **Why?** *Hy-gain* uses durable *tooled* components -- massive boom-to-mast bracket, heavy gauge element-to-boom clamps, thick-wall swaged tubing -- no failures!

**TH-11DX, $1399.95. 11-element, 4.0 kW PEP, 10,12,15,17,20 Meters.** *The choice of top DXers.* With 11-elements, excellent gain and 5-bands, the super rugged TH-11DX is the *"Big Daddy"* of all HF beams! Features low loss log-periodic driven array on all bands with monoband reflectors, BN-4000 high power balun, corrosion resistant wire boom support, hot dipped galvanized and stainless steel parts.

**TH-7DX, $1199.95. 7-Element, 1.5 kW PEP, 10,15,20 Meters.** 7-Elements gives you *the highest average gain of any Hy-gain* tri-bander! Dual driven for broadband operation without compromising gain. SWR less than 2:1 on all bands. Combined monoband and trapped parasitic elements give you an excellent F/B ratio.

**TH-3MK4, $569.95. 3-Element, 1.5 kW PEP, 10,15,20 Meters.** Gives most gain for your money in full-power, full-size *hy-gain* tri-bander! Impressive gain and a *whopping* average front-to-back ratio and still fits on an average size lot. 95 MPH wind survival.

**TH-3JRS, $439.95. Compact 3-Element, 600 W PEP, 10,15,20 Meters.** *Hy-gain's most popular and lowest-priced tri-bander fits smallest lot*, 14.75 ft turning radius, 21 lbs. Excellent gain and front-to-back let you compete with the "big guns"! 80 MPH wind survival.

## hy-gain Rotators . . . the first choice of hams around the world!

### HAM-IV . . . $729.95

***The most popular rotator in the world!*** For medium communications arrays up to 15 square feet wind load area. *New* 5-second brake delay! *New* Test/Calibrate function. *New* low temperature grease permits normal operation down to -30 degrees F. *New* alloy ring gear gives extra strength up to 100,000 PSI for maximum reliability. *New* indicator potentiometer. *New* ferrite beads reduce RF susceptibility. *New* Cinch plug plus 8-pin plug at control box. Dual 98 ball bearing race for load bearing strength and electric locking *steel* wedge brake prevents wind induced antenna movement. North or South center of rotation scale on meter, low voltage control, max mast size of 2 1/16 inches.

**HAM-VI, $909.95.** For medium arrays up to 15 sq. ft. wind load. Like HAM-IV but has *new **DCU-2** Digital Rotator Controller*. Just dial in your beam heading or let your computer control your antenna.

**HAM-VII, $999.95.** Like HAM VI but with ***DCU-3*** digital controller with *six programmable memories*.

### Tailtwister T-2X . . . $969.95

**For** large medium antenna arrays up to 20 sq. ft. wind load. Choose ***DCU-2 digital*** controller (T-2XD2) or *analog* control box (T-2X) with *new* 5-second brake delay and *new* Test/Calibrate function. Low temperature grease, alloy ring gear, indicator potentiometer, ferrite beads on potentiometer wires, *new* weatherproof AMP connectors plus 8-pin plug at control box, triple bearing race with 138 ball bearings for large load bearing strength, electric locking *steel* wedge brake, N or S center of rotation scale on meter, low voltage control, 2 1/16" max. mast.

**T-2XD2, $1079.95.** Tailtwister with ***DCU-2 digital*** controller.

**T-2XD3, $1139.95.** Tailtwister with ***DCU-3*** digital controller with *six programmable memories*.

**AR-40, $419.95.** For compact antenna arrays and FM/TV up to 3.0 sq. ft. wind load. Dual 12 ball-bearing race. Fully automatic.

**CD-45II, $519.95.** For antenna arrays up to 8.5 sq. ft. Bell rotator design gives total weather protection. Dual 58 ball bearing race.

## Digital Rotator Controller with *6 Programmable beam headings*

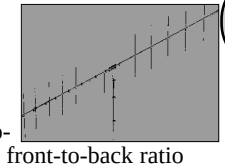
**New!**

DCU-3

**$519.95**

***New*** DCU-3 Digital Controller lets you program 6 beam headings! Gives you fully automatic or manual control of your hy-gain HAM or Tailtwister Rotators.

**Push** a memory button or dial in your beam heading or let *Ham Radio Deluxe* (or other program) control your DCU-3. Your antenna automatically rotates precisely and safely to your desired direction.



## hy-gain VHF/UHF Antennas

**V2R, $159.95.** 2-Meter *vertical* has two *in-phase* 5/8 Wave collinear radiators for exceptional high omnidirectional gain. It has two sets of quarter wave radials that decouple radiator from mast. Covers 138-175 MHz. SO-239, handles 500 Watts. 9 feet.

**V4R, $159.95.** UHF *vertical*. Like V2R but covers 400-475 MHz. Type N, handles 500 Watts, 4 foot.

**V42R, $219.95.** *Dual band* covers 144/440 MHz bands. Two 5/8 Wave collinears.

**VB-214FM, $149.95.** *14-element* 2-Meter FM *beam* antenna provides exceptional front-to-back ratio and maximum obtainable gains.

**VB-23FM, $69.95.** 3-element.

**VB-25FM, $79.95.** 5-element.

**VB-28FM, $129.95.** 8-element. Threaded stub for feedpoints. Accepts up to 2 inch mast.

**DB-2345, $139.95.** Dual band 144 (3-elements) 440 (5-elements) MHz.

**Free Hy-Gain Catalog**

# Pull Out the Muscle!

***Hear the roar and feel the POWER! Get that POWER you need to really bust through the pileups, win a few contests, work the world!!! Ameritron amplifiers will go a long way towards making those dreams a reality. We got an amplifier for every budget!***

## AMERITRON . . . 800 Watts . . . $1299!

***More hams use Ameritron AL-811/H amplifiers than any other amplifier in the world!***

AL-811H
**$1299**
Suggested Retail
*4-Tubes, 800 Watts*

AL-811
**$1199**
Suggested Retail
*3-Tubes, 600 Watts*

**Only** the Ameritron AL-811H gives you four *fully neutralized* 811A transmitting tubes. You get absolute stability and superb performance on higher bands that can't be matched by un-neutralized tubes.

**You** get a quiet desktop linear that's so compact it'll slide right into your operating position -- you'll hardly know it's there . . . until QRM sets in. And you can conveniently plug it into your nearest 120 VAC outlet -- no special wiring needed.

**You** get all HF band coverage (with license) -- including WARC and most MARS bands at 100% rated output. Ameritron's *Adapt-A-Volt*™ hi-silicon core power transformer has a special buck-boost winding that lets you compensate for high/low power line voltages.

**You** also get efficient full size heavy duty tank coils, slug tuned input coils, operate/standby switch, transmit LED, ALC, dual illuminated meters, QSK with optional QSK-5, pressurized cooling that you can hardly hear, full height computer grade filter capacitors and more. 13³/4Wx8Hx16D inches.

**AL-811, $1199.**

Like AL-811H, but has three 811A tubes, 600 Watts output.

## AMERITRON *no tune* Solid State Amplifiers

### ALS-500M 500 Watt Mobile Amp

ALS-500M
**$1099**
Suggested Retail

**500 W** PEP/ 400 W CW output, 1.5-22 MHz, instant bandswitching, no tuning, no warm-up. SWR, load fault, thermal overload protected. On/Off/Bypass switch. Remote on/off control. DC current meter. Extremely quiet fan. 13.8 VDC. 9Wx3¹/₂Hx15D in., 7 lbs. **ALS-500RC, $49,** Remote Head.

### ALS-606S 600 Watt 160-6M Amp

ALS-606S
**$2199**
Suggested Retail

**600 Watts** PEP/ 500W CW output, 160-6M with automatic instant bandswitching. Desktop. 9³/₄Wx7Hx14¹/₂D".14.2 lbs. Only 4 dB below 1500W -- less than an S-unit! **ALS-606, $2399,** like ALS-606S above, but has transformer power supply.

### *Desktop Kilowatt* Amplifier

AL-80B
**$1999**
Suggested Retail

**Whisper** quiet *desktop* amp plugs into 120 VAC to give *full* kilowatt SSB PEP output. Ameritron's exclusive *DynamicALC*™ doubles average SSB power out and *Instantaneous RF Bias*™ gives cooler operation. All HF bands. 850 Watts CW out, 500 Watts RTTY out, extra heavy duty power supply, 3-500G tube, 70% efficiency, tuned input, Pi/Pi-L output, inrush current protection, dual Cross-Needle meters, QSK compatible, 48 lbs. 14Wx8¹/2Hx15¹/2D". **2-year Ameritron warranty.**

### *ALS-1306 1200W 1.5-54 MHz Amp*

ALS-1306
**$3599**
Suggested Retail

**Ameritron's** *highest power* solid state FET amplifier gives you automatic bandswitching! Get 1200W PEP output on all bands, including 6-Meters. No tuning, no warm-up, no tubes to baby and no fuss! Eight rugged MRF-150 power FET's give outstanding reliability. Just 100 Watts drive gives full rated power MHz. Compact 10Wx6¹/2Hx18D in., just 22 lbs. **ALS-1300, $3199.** Like ALS-1306 but less automatic bandswitching and 6-M coverage.

### *Near Legal Limit* ™ Amplifier

AL-572
**$2199**
Suggested Retail

***Near Legal Limit*™** amp gives you 1300W PEP SSB power output for *60%* of the price of a full legal limit amp! Four rugged 572B tubes. Instant 3-second warm-up, 120 VAC. Desktop 14¹/₂Wx8¹/₂Hx15¹/₂D". 160-15M. 1000 Watt CW output. Tuned input, instantaneous RF Bias, dynamic ALC, parasitic killer, inrush protection, cross-needle meters, multi-voltage transformer.

### *HF Amps with* 3CX800A7 tube

AL-800
**$3199**
1 tube, 1250 W
Suggested Retail

AL-800H
**$4399**
2 tubes, 1.5 kW *Plus*
*Eimac*(R) *tubes*

**Desktop** 3CX-800A7 tubes cover 160-15M, WARC bands. Adjustable slug tuned input, grid protection, ALC control, vernier reduction drives, hefty 32 lb. transformer, high capacitance computer grade filter capacitors. Multi-voltage, dual cross-needle meters. 14¹/₄Wx8¹/₂Hx16¹/₂D".

## AMERITRON *full legal limit* amplifiers

***AMERITRON legal limit amps use a super heavy duty power transformers capable of 2.5 kW!***

### *Most powerful -- 3CX1500/8877*

AL-1500F
**$4199**
*3CX1500/8877* Tube

AL-1500
**$6199**
*Eimac*(R) tube

**Ameritron's** *most powerful* amplifier uses the herculean 3CX1500/8877 ceramic tube. 65 watts gives full legal output -- loafing with a 2500W power supply.

### *Toughest -- 3CX1200Z7*

AL-1200
**$4999**
Suggested Retail

**Ham** radio's *toughest* tube -- the *Eimac*(R) 3CX1200Z7. 50-Watt control grid dissipation. Super heavy duty power supply loafs at legal power -- delivers more than 2500 Watts PEP two tone output for a 1/2 hour.

### *Classic -- Dual 3-500Gs*

AL-82
**$3599**
Suggested Retail

**Gives** full legal output using a *pair* of *genuine* 3-500Gs. Competing linears using 3-500Gs *can't* give you 1500 Watts because their lightweight power supplies *can't* use these tubes to their full potential.

## Ameritron brings you the finest high power accessories!

***ARB-704 amp-to-rig interface . . . $84.95***

Protects rig from keying line transients. Easy rig hookup.

***RCS-4 Remote Coax Switch…$219.95***

Use 1 coax for **4** antennas. No control cable needed. SWR <1.25, 1.5 - 60 MHz. Useable to 100 MHz.

***RCS-8V Remote Coax Switch...$249.95***

Replace **5** coax with 1! 1.2 SWR, 250 MHz. Useable to 450 MHz. <.1 dB loss, 1kW@150MHz.

***RCS-10 Remote Coax Switch...$249.95***

Replace **8** coax with 1! SWR<1.3 to 60 MHz. **RCS-10L, $289.95** with lightning arrestors.

# New! Cushcraft R9 . . . *80-6 Meters*

## *80 Meters . . . No Radials . . . 1500W*

***Cushcraft's world famous R8 now has a big brother!***

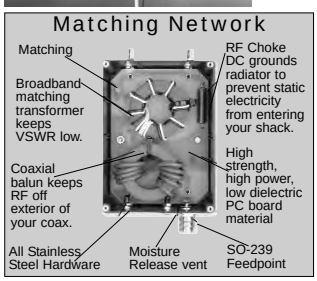
**Big** Brother R9 now includes 75/80 Meters for local ragchewing and worldwide low band DX *without radials*!

**It's** omni-directional low angle radiation gives you exciting and easy DX on all 9 bands: 75/80, 40, 30, 20, 17, 15, 12, 10 and 6 Meters with low SWR. QSY instantly -- no antenna tuner needed.

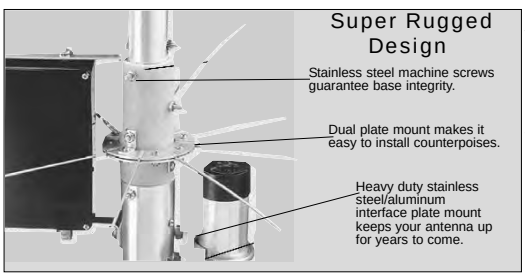
**Use** full *1500 Watts* SSB/CW when the going gets tough to break through pileups/poor band conditions.

**The** R9 is super easy to assemble, installs just about anywhere, and its low profile blends inconspicuously into the background in urban and country settings alike.

**Compact Footprint:** Installs in an area about the size of a child's sandbox -- no ground radials to bury with all RF-energized surfaces safely out of reach.



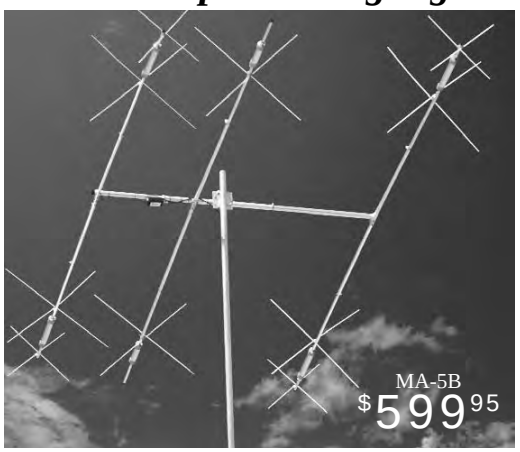
**Rugged Construction:** Thick fiberglass insulators, all-stainless steel hardware and 6063 aircraft-aluminum tubing is double or triple walled at key stress points to handle anything Mother Nature can dish out.



**31.5** feet tall, 25 lbs. Mounting mast 1.25 to 2 inches. Wind surface area is 4 square feet.

**R8, $619.95.** Like R9 antenna but less 75/80 Meters.

**R-8TB, $109.95.** Tilt-base lets you tilt your antenna up/down easily by yourself to work on.



**R-8GK, $89.95.** Three-point guy kit for high winds.

# MA-5B *5-Band* Beam

## *Small Footprint -- Big Signal*

**The** MA-5B is one of Cushcraft's most popular HF antennas, delivering solid *signal-boosting directivity* in a bantam-weight package. Mounts on roof using standard TV hardware. Perfect for exploring exciting DX without the high cost and heavy lifting of installing a large tower and full-sized array. Its 7 foot 3-inch boom has less than 9 feet of turning radius. Contest tough -- handles 1500 Watts.

**The** unique MA-5B gives you 5-bands, automatic band switching and easy installation in a compact 26-pound package. On 10, 15 and 20 Meters the end elements become a two-element Yagi that delivers solid power-multiplying gain over a dipole on all three bands. On 12 and 17 Meters, the middle element is a highly efficient trap dipole. When working DX, what really matters are the interfering signals and noise you *don't hear*. That's where the MA-5B's impressive side rejection and front-to-back ratio really shines. *See* ***cushcraftamateur.com*** *for gain figures.*

# Cushcraft 10, 15 & 20 Meter Tribander Beams

**Only** the best tri-band antennas become DX classics, which is why the Cushcraft World-Ranger A4S, A3S, and A3WS go to the head of the class. For more than 30 years, these pace-setting performers have taken on the world's most demanding operating conditions and proven themselves every time. The key to success comes from attention to basics. For example, element length and spacing has been carefully refined over time, and high-power traps are still hand-made and individually tuned using laboratory-grade instruments. All this attention to detail means low SWR, wide bandwidth, optimum directivity, and high efficiency -- important performance characteristics you rely on to maintain regular schedules, rack up impressive contest scores, and grow your collection of rare QSLs!

It goes without saying that the World-Ranger lineup is also famous for its rugged construction. In fact, the majority of these antennas sold years ago are still in service today! Conservative mechanical design, rugged over-sized components, stainless-steel hardware, and aircraft-grade 6063 make all the difference.

**The** 3-element A3S/A3WS and 4-element A4S are world-famous for powerhouse gain and super performance. **A-3WS**, **$569.95,** 12/17 M. **30/40 Meter** *add-on kits* available.

# Cushcraft Dual Band Yagis

***One Yagi for Dual-Band FM Radios***

Dual-bander VHF rigs are the norm these days, so why not compliment your FM base station with a dual-band Yagi? Not only will you eliminate a costly feed line, you'll realize extra gain for digital modes like high-speed packet and D-Star! Cushcraft's A270-6S provides three elements per band and the A270-10S provides five for solid point-to-point performance. They're both pre-tuned and assembly is a snap using the fully illustrated manual.

# Cushcraft Famous ***Ringos*** Compact FM Verticals

**W1BX's** famous *Ringo* antenna has been around for a long time and remains unbeaten for solid reliability. The Ringo is broad-banded, lighting protected, extremely rugged, economical, electrically bullet-proof, low-angle, and more -- but mainly, it just plain works! To discover why hams and commercial two-way installers around the world still love this antenna, order yours now!

# HAM RADIO OUTLET®

WWW.HAMRADIO.COM

## FAMILY OWNED AND OPERATED SINCE 1971

**FTDX101MP** | *200W HF/50MHz Transceiver*

• Hybrid SDR Configuration • Unparalleled 70 dB Max. Attenuation VC-Tune • New Generation Scope Display 3DSS • ABI (Active Band Indicator) & MPVD (Multi-Purpose VFO Outer Dial) • PC Remote Control Software to Expand the Operating Range • Includes External Power With Matching Front Speaker

**FTDX10** | *HF/50MHz 100 W SDR Transceiver*

• Narrow Band and Direct Sampling SDR • Down Conversion, 9MHz IF Roofing Filters Produce Excellent Shape Factor • 5" Full-Color Touch Panel w/3D Spectrum Stream • High Speed Auto Antenna Tuner • Microphone Amplifier w/3-Stage Parametric Equalizer • Remote Operation w/optional LAN Unit (SCU-LAN10)

**FT-991A** | *HF/VHF/UHF All ModeTransceiver*

Real-time Spectrum Scope with Automatic Scope Control • Multi-color waterfall display • State of the art 32-bit Digital Signal Processing System • 3kHz Roofing Filter for enhanced performance • 3.5 Inch Full Color TFT USB Capable • Internal Automatic Antenna Tuner • High Accuracy TCXO

**FTDX101D** | *HF + 6M Transceiver*

• Narrow Band SDR & Direct Sampling SDR • Crystal Roofing Filters Phenomenal Multi-Signal Receiving Characteristics • Unparalleled - 70dB Maximum Attenuation VC-Tune • 15 Separate (HAM 10 + GEN 5) Powerful Band Pass Filters • New Generation Scope Displays 3-Dimensional Spectrum Stream

**FT-891** | *HF+50 MHz All Mode Mobile Transceiver*

Rugged Construction in an Ultra Compact Body • Stable 100 Watt Output with Efficient Dual Internal Fans • 32-Bit IF DSP Provides Effective and Optimized QRM Rejection • Large Dot Matrix LCD Display with Quick Spectrum Scope • USB Port Allows Connection to a PC with a Single Cable • CAT Control, PTT/RTTY Control

**FTM-300DR** | *C4FM/FM 144/430MHz Dual Band*

• 50W Reliable Output Power • Real Dual Band Operation (V+V, U+U, V+U, U+V) • 2-inch High-Res Full Color TFT Display • Band Scope • Built-in Bluetooth • WiRES-X Portable Digital Node/Fixed Node with HRI-200

**FT-2980R** | *Heavy-Duty 80W 2M FM Transceiver*

• Massive heatsink guarantees 80 watts of solid RF power • Loud 3 watts of audio output for noisy environments • Large 6 digit backlit LCD display for excellent visibility • 200 memory channels for serious users

**FT-818ND** | *HF/6M/2M/440 All Mode Portable Xcvr*

• Ultra-Compact/Portable • Multi-Color Easy to See LCD • 208 Memory Channels/10 Memory Groups • Built-in Electronic Keyer • Internal Battery Operation Capability • Two Antenna Connectors • Built-in High Stability Oscillator ±0.5 ppm

**FTM-400XD** | *2M/440 Mobile*

• Color display-green, blue, orange, purple, gray • GPS/APRS • Packet 1200/9600 bd ready • Spectrum scope • Bluetooth • MicroSD slot • 500 memory per band

**FT-70DR** *C4FM/FM 144/430MHz Xcvr*

• System Fusion Compatible • Large Front Speaker delivers 700 mW of Loud Audio Output • Automatic Mode Select detects C4FM or Fm Analog and Switches Accordingly • Huge 1,105 Channel Memory Capacity • External DC Jack for DC Supply and Battery Charging

**FT-3DR** *C4FM/FM 144/430 MHz Xcvr*

• High Res Full-Color Touch Screen TFT LCD Display • Easy Hands-Free Operation w/Built-In Bluetooth Unit • Built-In High Precision GPS Antenna • 1200/9600bps APRS Data Communications • Simultaneous C4FM/C4FM Standby • Micro SD Card Slot

**FT-65R** | *144/430 MHz Transceiver*

Compact Commercial Grade Rugged Design • Large Front Speaker Delivers 1W of Powerful Clear Audio • 5 Watts of Reliable RF Power Within a compact Body • 3.5-Hour Rapid Charger Included • Large White LED Flashlight, Alarm and Quick Home Channel Access

**FT-60R** | *2M/440 5W HT*

• Wide receiver coverage • AM air band receive • 1000 memory channels w/alpha labels • Huge LCD display • Rugged die-cast, water resistant case • NOAA severe weather alert with alert scan

## *FREE SHIPPING AND FAST DELIVERY!

**IC-9700** | *All Mode Tri-Band Transceiver*

• VHF/UHF/1.2GHz • Direct Sampling Now Enters the VHF/UHF Arena • 4.3" Touch Screen Color TFT LCD • Real-Time, High-Speed Spectrum Scope & Waterfall Display • Smooth Satellite Operation

**IC-7851** | *HF/50MHz Transceiver*

• 1.2kHz "Optimum" roofing filter • New local oscillator design • Improved phase noise • Improved spectrum scope • Dual scope function • Enhanced mouse operation for spectrum scope

**IC-7300** | *HF/50MHz Transceiver*

• RF Direct Sampling System • New "IP+" Function • Class Leading RMDR and Phase Noise Characteristics • 15 Discrete Band-Pass Filters • Built-In Automatic Antenna Tuner

**IC-7610** | HF/50 MHz *All Mode Transceiver*

• Large 7-inch color display with high resolution real-time spectrum scope and waterfall • Independent direct sampling receivers capable of receiving two bands/two modes simultaneously

**IC-R8600** | *Wideband SDR Receiver*

10 kHz to 3 GHz Super Wideband Coverage • Real-time Spectrum Scope w/Waterfall Function • Remote Control Function through IP Network or USB Cable • Decodes Digital Incl P25, NXDN™, D-STAR • SD Card Slot for Receiver Recorder

**IC-718** | *HF Transceiver*

• 160-10M** • 100W • 12V operation • Simple to use • CW Keyer Built-in • One touch band switching • Direct frequency input • VOX Built-in • Band stacking register • IF shift • 101 memories

**IC-705** | HF/50/144/430 MHz *All Mode Transceiver*

• RF Direct Sampling • Real-Time Spectrum Scope and Waterfall Display • Large Color Touch Screen • Supports QRP/QRPp • Bluetooth® and Wireless LAN Built-in

**IC-7100** | *All Mode Transceiver*

• HF/50/144/430/440 MHz Multi-band, Multi-mode, IF DSP • D-STAR DV Mode (Digital Voice + Data) • Intuitive Touch Screen Interface • Built-in RTTY Functions

**IC-2730A** | *VHF/UHF Dual Band Transceiver*

• VHF/VHF, UHF/UHF simultaneous receive • 50 watts of output on VHF and UHF • Optional VS-3 Bluetooth® headset • Easy-to-See large white backlight LCD • Controller attachment to the main Unit

**ID-5100A Deluxe**

*VHF/UHF Dual Band Digital Transceiver*

• Analog FM/D-Star DV Mode • SD Card Slot for Voice & Data Storage • 50W Output on VHF/UHF Bands • Integrated GPS Receiver • AM Airband Dualwatch

**ID-4100A** | *VHF/UHF Dual Band Digital Xcvr*

• Compact, Detachable Controller for Flexible Installation • DV/FM Near Repeater Search Function • Apps for iOS™ and Android™ devices • Wireless Operation with VS-3 & UT-137 Bluetooth® Headset & Module • MicroSD Card Slot

**IC-2300H** | *VHF FM Transceiver*

• 65W RF Output Power • 4.5W Audio Output • MIL-STD 810 G Specifications • 207 alphanumeric Memory Channels • Built-in CTCSS/DTCS Encode/Decode • DMS

**IC-V86** | *VHF 7W HT*

• 7W OutputPower Plus New Antenna Provides 1.5 Times More Coverage • More Audio, 1500 mW Audio Output • IP54 & MIL-STD 810G–Rugged Design Against Dust & Water • 19 Hours of Long Lasting Battery Life • 200 Memory Channels, 1 Call Channel & 6 Scan Edges

**IC-R30** | *Digital/Analog Wideband Xcvr*

• 100 kHz to 3.3 GHz Super Wideband Coverage • P25 (Phase 1), NXDNTM, dPMRTM, D-STAR Mode • 2.3" Large LCD Display & Intuitive User Interface • MicroSD Card Slot for Voice & Data Storage • USB Charging & PC Connection

**ID-52A** | *VHF/UHF D-STAR Portable*

NEW

• Bluetooth® Communication • Simultaneous Reception in V/V, U/U, V/U and DV/DV • Enriched D-STAR® Features Including the Terminal Mode/Access Point Mode • UHF (225~374.995MHz) Air Band Reception

Prerelease. This device has not been approved by the F.C.C.

## Your New Partner for Field Operations

*The antenna and antenna connector in the photo are after-market products.

- **HF/50/144/440 MHz Multimode, including the D-STAR DV Mode**
- **RF Direct Sampling System**
  * The down-conversion IF sampling method is used for 25 MHz and above.
- **Real-Time Spectrum Scope and Waterfall Display**
- **Large Touch Screen Color Display**
- **Compact and Lightweight Design** * Approximately 1.1 kg, including the battery pack.
- **BP-272 Battery Pack or 13.8 V DC External Power Source**
- **Maximum Output Power 5 W (BP-272), 10 W (13.8 V DC)**

**Making your field operation more fun and stylish**

Multi-Function Backpack **LC-192**

**Supplied Accessories**
HM-243 Speaker-microphone,
BP-272 Li-ion Battery Pack,
OPC-2421 DC Power Cable

**Be Active!** *In the field with the IC-705*

**WHEN YOU TAP INTO OUR GENIUS SOLUTIONS, SUDDENLY EVERYTHING AROUND YOU FEELS SMARTER.**

Genius products are engineered to work so well in tandem, expanding your station's ability to deliver exceptional experiences and exponential performance increases. Add a Power Genius XL and get the only legal-limit SO2R/Multi-Single capable HF/6M amplifier on the market. Add a Tuner Genious XL and gain not only super-fast, legal-limit impedance matching on antennas with up to 10:1 SWR but then pick up 70dB of port isolation for seamless SO2R operation. Add an Antenna Genius and enjoy frequency-driven contest-class SO2R antenna switching and super-station automation capabilities. With integration this easy, our Genius Solutions help you realize the potential of your station, making you genius-level smart along the way. Learn more at **FlexRadio.com**

# The SteppIR Advantage

## PROBLEM SOLVED!

Yagi antennas are basically single frequency devices that work well only over a very narrow range, typically 0.5% change in frequency. Fixed length yagis compensate by using a variety of techniques, all of which result in serious degradation of performance, especially in Front to Rear rejection, and added complexity, size, and weight. Dipoles have a much broader bandwidth but still cannot cover the entire 80m and 40m bands and maintain a low SWR (<1.5:1). Our patented solution is to simply adjust all of the antenna elements to the optimal length for the desired frequency with none of the compromises in performance that all fixed antennas require. This is accomplished remotely using an electronic controller that can automatically follow the radios' frequency. SteppIR antennas enjoy optimal performance on all frequencies within their specified frequency range (varies by model), and that includes non-ham radio frequencies as well!

## THE INHERENT ADVANTAGES OF A STEPPIR:

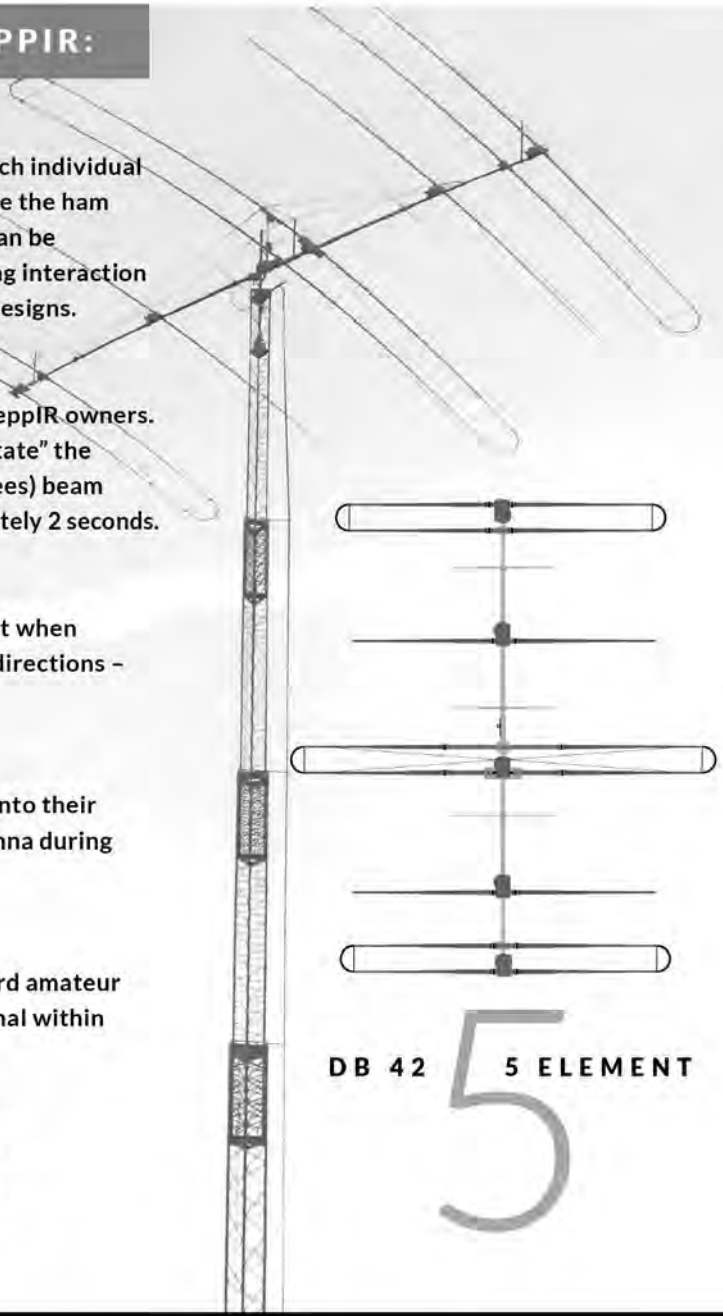
### Create/Modify Mode

The create modify mode allows the user to change the length of each individual antenna element on all bands of operation -and frequencies outside the ham bands as well – and then save the new antennas to memory. This can be incredibly useful to "tune" out potential objects that may be causing interaction with the SteppIR antenna, or to create your own custom antenna designs.

### 180 Degree Mode

The 180 degree mode feature is one of the most popular among SteppIR owners. For our Yagi antennas, this feature allows a user to electrically "rotate" the antenna from the forward beam heading, to the reverse (180 degrees) beam heading, with a click of a button – the entire process takes approximately 2 seconds.

### Bi-Directional Mode



The bi-directional mode works similarly to the 180 function, except when enabled, the Yagi antenna will now be operating with gain in both directions – forward and backwards, simultaneously!

### Retract Elements

With a touch of a button, SteppIR antennas can be fully retracted into their housing, which helps to protect the most valuable part of the antenna during extreme weather events.

### Emergency Communications

Many times, emergency communications occur outside the standard amateur radio allocated bands of operation. All SteppIR antennas are optimal within the entire scope of their specified frequency range.

# *Enjoy "noise free" receive audio with..*
# *..a bhi DSP noise cancelling product!* bhi

## ParaPro EQ20 Audio DSP range with parametric equalisation

- 20W audio and parametric equalisation on all units
- Greatly improved audio for those with hearing loss
- Simple control of all DSP functions
- Two separate mono inputs or one stereo input
- Basic 20W EQ units: EQ20, EQ20B* (use with your Dual In-Line or Compact In-Line unit)
- 20W DSP noise cancelling EQ versions: EQ20-DSP and EQ20B*-DSP * Denotes Bluetooth on input

***Read the excellent EQ20-DSP review in December 2019 QST!***

## High-performance audio processing...
## ...with first class DSP noise cancelling...
## ...for a great listening experience

### Dual In-Line

Fully featured flexible dual channel DSP noise cancelling unit - 8 Filter levels 9 to 40dB - 3.5mm mono or stereo inputs - Line level input/output - 7 watts mono speaker output - Headphone socket - Suitable for all types of radio incl' SDR - Easy to use controls for quick and easy operation - Enjoy clear intelligble "noise-free"speech from your radio - Replacement for bhi NEIM1031 In-Line

### Compact In-Line

Easy to use in-line DSP noise cancelling unit with simple "real-time" control of audio and functions - Works on all radio bands

- Powerful high-performance audio processor
- Unique DSP noise cancelling technology
- Remove noise and interference - Hear weak signals clearly - Rotary encoders perform all functions
- Easy to use with "real time" adjustments
- Use with headphones or a loudspeaker

### NES10-2MK4

**New improved design**

- 5W audio - Latest bhi DSP noise cancelling
- 8 filter levels 8 to 40dB
- Three position switch for off/audio bypass mode, power on and DSP filter on - LEDs for Power on, filter on and audio overload
- Headphone socket

*Read the excellent NES10-2MK4 review in May QST page 48*

### *New* DESKTOP MKII

***Latest bhi DSP noise cancelling technology for even better receive audio***

- 10W Amplified DSP noise cancelling base station speaker
- "Real-time" control of all functions
- 8 filter levels 9-40dB
- Speaker level and line level input sockets
- Suitable for all radios incl' SDR, Elecraft and FlexRadio products

Molex connector: 24.9
Monolithic microwave IC (MMIC): 22.22
Monopole: 21.21
Monte Carlo analysis: 6.1
Moonbounce (*see* EME): 1.17
Morse code: 1.11

MOSFET: 2.30, 4.25
Depletion mode: 4.25
Electrostatic discharge (ESD): 4.26
Enhancement mode: 4.25
Pass transistor: 7.17
Power: 4.26
MOSFET, RF Power
Data sheet parameters and ratings: 17.29
Gate structures: 17.27
LDMOS vs VDMOS: 17.28, 17.39
Linearity: 17.38
RF power amplifier design: 17.27ff
Thermal design: 17.29
Transfer characteristics: 17.31
Voltage ratings: 17.28
MP3 compression: 15.4
MSFK16: 15.9
Convolution code: 15.10
Fast Fourier Transform (FFT): 15.11
Gray code: 15.10
Hamming distance: 15.11
Interleaver: 15.10
Modulation: 15.11
Quadbit, nibble: 15.10
MSK (*see* Minimum-shift keying)
MSK144: 15.16
Meteor scatter: 15.16
MT63: 15.12
Error-correction: 15.12
Latency: 15.12
Navy MARS: 15.12
Noise immunity: 15.12
Tuning error: 15.12
Walsh function: 15.12
MUF (*see* Maximum usable frequency)
Multi-protocol controller (MPC): 15.20
Multi-rate conversion: 8.21
Multimeter: 25.3, 26.3
Input impedance: 25.7
Specifications: 25.5
Use of: 25.5
Used and surplus: 25.7
Multimode communications processor (MCP): 15.19
Multipath propagation: 19.29
Multiplier-accumulator (MAC): 8.16, 8.24
*MultiPSK*: 15.13
Mutual inductance (M): 2.23

## N

N connector: 24.10
Narrowband noise: 27.17
National Bureau of Standards (NBS): 25.1
National Electrical Code (NEC): 28.2, 28.6
Antennas: 28.3
National Institute of Standards and Technology (NIST): 25.1
National Recognized Testing Laboratories (NRTL): 28.2
National Traffic System (NTS): 1.20
Navigation data: 16.9
Near field: 25.38
Near-vertical incidence skywave (NVIS): 19.9, 21.16
*NEC* modeling engine: 21.20
Necessary bandwidth (*see also* Bandwidth): 13.1
Neper: 20.9
Netlist: 6.6, 23.30
Network analyzer: 25.25ff
Neutralization: 17.22
NiCd (NiCad) battery: 7.36
Charging: 7.40
NiMH battery: 7.36
Charging: 7.41
NIST traceable standard: 25.1
Node (circuit): 2.5
Noise: 3.37, 5.31ff
AM noise and FM signals: 11.8
Antenna layout: 13.26
Background: 5.34
Broadband: 27.17
Cosmic: 19.32
Factor, figure: 5.32
Friis formula: 5.32
From losses: 5.32
Gain: 5.32
Gap noise: 27.18
Ignition: 27.48
Image response: 5.33
Johnson, Johnson-Nyquist: 5.31
Man-made: 19.31
Narrowband: 27.17
Of cascaded amplifiers: 5.32
Of preamplifiers: 5.33
Power: 5.31
Simulation: 5.17
SINAD: 5.32
Sources: 12.2
Sun: 5.33
Temperature: 5.31
White: 5.31
Noise bandwidth: 25.31
Noise blanker: 12.53
Noise bridge: 25.40
Noise canceling: 12.54
Noise factor (F): 5.32
Noise figure (NF): 5.32, 25.31
Measuring: 25.27
Preamplifier location: 12.4
Relationship to noise temperature (Table): 22.43
Noise limiter: 12.53
Noise power ratio (NPR): 12.10
Noise reduction: 12.55
Noise source: 25.27
Noise source signature: 27.21
Noise temperature: 12.3
Relationship to noise figure (Table): 22.43
Nominal value: 4.2, 22.2
Non-inverting amplifier: 4.46
Non-linear junction: 27.19
Northern California DX Foundation (NCDXF) beacons: 19.21
Norton equivalent circuit: 2.9
Norton's Theorem: 2.8
Notch filter: 10.3
DSP: 12.55
NTSC: 11.19
NVIS (*see* Near-vertical incidence skywave)
Nyquist
Frequency: 8.7, 8.19
Rate: 8.7, 8.19
Nyquist filter: 11.26
Nyquist sampling criterion: 8.19
Nyquist sampling theorem: 8.7

## O

O wave: 19.9
Occupied bandwidth: 13.1
Octal: 8.6
Oersted (Oe): 2.19
OFDM (*see* Orthogonal frequency-division multiplexing)
Off-center fed (OCF) dipole: 21.9, 21.16
Offset (repeater): 18.4
Offset quadrature phase-shift keying (OQPSK): 15.16
Ohm (Ω): 2.4
Ohm's law: 2.4
Power formulas: 2.10
Ohmmeter: 25.3
Oil-filled capacitor: 7.30
Olivia: 15.12
MFSK: 15.12
Orthogonal tones: 15.12
Telemetry: 16.11

On-off keying (OOK): 11.5
Open-collector output: 4.48
Open-wire line: 20.2, 20.8
Operating
  Award: 1.15
  Nets: 1.4, 1.20
  Ragchewing: 1.4
Operational amplifier (op-amp): 4.45
  Active filter: 4.49
  Common-mode rejection ratio (CMRR): 4.45
  Comparator: 4.47
  Compensation (frequency): 4.45
  Difference amplifier: 4.47
  Differential amplifier: 4.47
  Gain: 4.45
  Gain-bandwidth product ($F_T$, GBW): 4.45
  Input and output impedance: 4.46
  Input bias current: 4.46
  Input offset voltage: 4.46
  Instrumentation amplifier: 4.47
  Inverting and non-inverting amplifier: 4.46
  Log amplifier: 4.50
  Open-loop gain: 4.46
  Peak detector: 4.49
  Power-supply rejection ratio (PSRR): 4.46
  Rail-to-rail: 4.46
  Rectifier circuit: 4.49
  Specifications: 22.32
  Summing amplifier: 4.47
  Summing junction: 4.46
  Transimpedance: 16.5
  Unity-gain buffer: 4.46
  Use of feedback: 4.47
  Virtual ground: 4.47
  Voltage-current converter: 4.50
  Voltage-follower circuit: 4.46, 4.47
Optoisolator: 4.29, 4.55
  AC load, driving: 4.55
  Circuit design: 4.29
  Current transfer ratio (CTR): 4.29
  Relay, driving: 4.55
Order (filter): 10.4

  Multiplier resistor: 25.8
  RF: 25.65
  Sensitivity, ohms-per-volt: 25.3
  Vacuum-tube, VTVM: 25.3
  VOM (volt-ohm-meter): 25.3
Volume Meshing
  Finite difference time domain (FDTD): 6.16
  Finite element method (FEM): 6.18
  Transmission line method (TLM): 6.18
Volunteer Consulting Engineer (VCE), ARRL: 28.1
Volunteer Examiner (VE): 1.5
VOM (volt-ohm-meter): 25.3
Von Neumann architecture: 8.15
VOX (*see* Voice-operated transmit)
VSB, 8-VSB (see Vestigial sideband)
VSWR (*see* Standing-wave ratio)

## W

W1AW: 1.7
*W6ELProp*: 19.22
Waterfall display: 14.8, 15.5
Watt (W): 2.9
Watt-hour (Wh): 2.9
Wattmeter: 26.4
  Directional: 20.5, 25.20
  Reflectometer: 20.5
Wave cyclone: 19.26
Waveforms
  Complex: 3.4
  Ramp wave: 3.4
  Sawtooth wave: 3.4
  Sine wave: 3.1
  Square wave: 3.5
Waveguide: 20.32, 20.32ff
  Coax-to-waveguide adapters: 25.29
  Coupling to: 20.34
  Cutoff frequency: 20.30
  Dimensions: 20.33
  Dominant mode: 20.32
  Modes (TM, TE): 20.33
  Practical application: 20.35
  Termination: 20.34
Wavelength (λ): 3.40, 19.1
Wavemeter: 25.11
Waveshaping (CW keying): 13.18
Weather station: 16.23
Weatherproofing
  Coaxial cable: 20.8
Weaver method (SSB generation): 11.17, 13.22
*Webench* by National Semiconductor: 10.16
Weber (Wb): 2.19
Weston, Edward: 25.3
Wheatstone bridge: 25.3
Whip antenna: 21.42ff
  Loading: 21.43
White noise: 5.31
Whitten, David KDØEAG: 15.17
Wien bridge: 25.17
  Oscillator: 25.53
Wilkinson combiner and divider: 25.29
Wind load (rotator): 21.72
Windowing (digital filter): 10.18
Winlink: 1.12, 15.27ff
  *Airmail*: 15.28
  B2F: 15.27
  Common Message Servers (CMS): 15.27
  Paclink: 15.27
  PACTOR: 15.26
  PMBO: 15.28
  Radio Message Server (RMS): 15.27
  TELNET: 15.28
WINMOR: 1.12, 15.24
  Comparison to PACTOR: 15.24
  SCAMP: 15.24
  TNC interface: 15.25
Wire
  Magnet wire: 20.28
  Resistance: 4.1
  Size (mobile installations): 24.13
  Specifications: 22.39
Wire antenna construction: 21.9
*WIRES-X* (Yaesu): 18.21
Words per minute (WPM): 11.6
*WSJT-X*: 1.12, 15.14, 19.20
  Bandwidth: 15.14
  Clock synchronization: 15.14
  Fast modes: 15.16
  Forward error correction (FEC): 15.14
  Maidenhead grid locators: 15.14
  Message compression: 15.14
  Meteor scatter: 19.16
  Slow modes: 15.14
WSPR (Weak Signal Propagation Reporter): 15.16, 19.20
  Telemetry: 16.11
Wullenweber antenna: 21.68
WWV, WWVH: 19.22, 25.12
  Propagation forecast: 19.10, 19.13

## X

X wave: 19.9

## Y

Y (admittance) parameters: 5.36
Yagi, Yagi-Uda antenna: 21.30ff
  Director: 21.31
  Parasitic excitation: 21.31
  Reflector: 21.31
  Stacking: 21.57
  VHF/UHF: 21.57ff
YIG-tuned oscillator: 9.26

## Z

Z (impedance) parameters: 5.36
Z-transform: 10.22
Zener diode: 4.21
  Specifications: 22.18
  Voltage regulator: 7.15
Zepp (antenna): 21.8
Zero (transfer function): 3.34
Zero bias: 17.2
Zero-order hold: 8.20
Zero-stuffing: 8.21

14 Glossary of Space Communications Terminology

# Space Communications

Radio amateurs point their antennas skyward to talk via communications satellites built by groups of interested and talented hams. In the first part of this supplement, Steve Ford, WB8IMY, provides some background and shows what you need to get involved with amateur satellites.

The EME section, written by Joe Taylor, K1JT, discusses the requirements for successful contacts via the EME path. K1JT gratefully acknowledges input and advice for the EME section from Allen Katz, K2UYH, Marc Franco, N2UO, Peter Blair, G3LTF, Graham Daubney, F5VHX, Lionel Edwards, VE7BQH, Ian White, GM3SEK, Leif Asbrink, SM5BSZ and Rex Moncur, VK7MO. A glossary of space communications terms may be found at the end of this chapter. Unless otherwise noted, references to other chapters refer to the chapters in the print version of the *ARRL Handbook*.

## 1 Amateur Satellite History

The story of amateur radio satellites is as old as the Space Age itself. The Space Age is said to have begun on October 4, 1957. That was the day when the Soviet Union shocked the world by launching Sputnik 1, the first artificial satellite. Hams throughout the world monitored Sputnik's telemetry beacons at 20.005 and 40.002 MHz as it orbited the Earth. During Sputnik's 22-day voyage, amateur radio was in the media spotlight since hams were among the few civilian sources of news about the revolutionary spacecraft.

Almost four months later, the United States responded with the launch of the Explorer 1 satellite on January 31, 1958. At about that same time, a group of amateur radio operators on the West Coast began considering the possibility of a ham radio satellite. This group later organized itself as Project OSCAR (OSCAR is an acronym meaning Orbiting Satellite Carrying Amateur Radio) with the expressed aim of building and launching amateur satellites. (See the sidebar "When Does a Satellite Become an OSCAR?")

After a series of high-level exchanges with the American Radio Relay League and the United States Air Force, Project OSCAR secured a launch opportunity. The first amateur radio satellite, known as OSCAR 1, would "piggyback" with the Discoverer 36 spacecraft being launched from Vandenberg Air Force Base in California. Both "birds" (as satellites are called among their builders and users) successfully reached low Earth orbit on the morning of December 12, 1961.

OSCAR 1 weighed only 10 pounds. It was built, quite literally, in the basements and garages of the Project OSCAR team. It carried a small beacon transmitter that allowed ground stations to measure radio propagation through the ionosphere. The beacon also transmitted telemetry indicating the internal temperature of the satellite.

OSCAR 1 was an overwhelming success. More than 570 amateurs in 28 countries forwarded observations to the Project OSCAR data collection center. OSCAR 1 lasted only 22 days in orbit before burning up as it reentered the atmosphere, but amateur radio's "low tech" entry into the high tech world of space travel had been firmly secured. When scientific groups

### When Does a Satellite Become an OSCAR?

While worldwide AMSAT organizations are largely responsible for the design and construction of the modern day amateur radio satellites, the original "OSCAR" designation is still being applied to many satellites carrying amateur radio. However, most amateur radio satellites are not usually assigned their sequential OSCAR numbers until *after* they successfully achieve orbit and become operational. Even then, an OSCAR number is only assigned after its sponsor formally requests one.

For example, let's make up a satellite and call it ROVER. The ROVER spacecraft won't receive an OSCAR designation until (1) it reaches orbit and (2) its sponsor submits a request. Now let's presume that ROVER makes it into orbit and the OSCAR request is made and granted. ROVER is now tagged as OSCAR 99 and its full name becomes ROVER-OSCAR 99. You'll find, however, that many hams will abbreviate the nomenclature. Some will simply call the satellite ROVER, or OSCAR 99. They may even abbreviate its full name to just RO-99.

If a satellite subsequently fails in orbit, or it re-enters the Earth's atmosphere, its OSCAR number is usually retired, never to be issued again.

asked the Air Force for advice on secondary payloads, the Air Force suggested they study the OSCAR design. What's more, OSCAR 1's bargain-basement procurement approach and management philosophy would become the hallmark of all the OSCAR satellite projects that followed, even to this day.

Since then, amateurs have successfully built and launched dozens of satellites, each one progressively more sophisticated than the last.

## 1.1 AMSAT

Much of the amateur satellite progress has been spearheaded by the Radio Amateur Satellite Corporation, better known as *AMSAT*. The original AMSAT was formed in Washington, DC in 1969 as an organization dedicated to fostering an amateur radio presence in space. The AMSAT model quickly became international with many countries creating their own AMSAT organizations, such as AMSAT-UK in England, AMSAT-DL in Germany, BRAMSAT in Brazil and AMSAT-LU in Argentina. All of these organizations operate independently but may cooperate on large satellite projects and other items of interest to the worldwide amateur radio satellite community. Because of the many AMSAT organizations now in existence, the US AMSAT organization is frequently designated AMSAT-NA.

Since the very first OSCAR satellites were launched in the early 1960s, AMSAT's international volunteers have pioneered a wide variety of new communications technologies. These breakthroughs have included some of the very first satellite voice transponders as well as highly advanced digital "store-and-forward" messaging transponder techniques. All of these accomplishments have been achieved through close cooperation with international space agencies that often have provided launch opportunities at significantly reduced costs in return for AMSAT's technical assistance in developing new ways to launch paying customers.

AMSAT's major source of operating revenue is obtained by offering memberships in the various international AMSAT organizations. Membership is open to radio amateurs and to others interested in the amateur exploration of space. Modest donations are also sought for tracking software and other satellite related items. In addition, specific spacecraft development funds are established from time to time to help fund major AMSAT spacecraft projects through donations. In addition to money, AMSAT makes creative use of leftover materials donated from aerospace industries worldwide.

The AMSAT-NA organization, from the president on down to the workers designing and building space hardware, all donate their time and talents to the organization.

## 1.2 Amateur Satellites Today

When this edition of the *Handbook* went to press, there were nearly 180 active amateur radio satellites in orbit (see **Table 1**), not counting the amateur radio presence aboard the International Space Station. All of these are low Earth orbiting (LEO) spacecraft that

**Table 1**
**Currently Active Satellites**

*Note: While the satellites listed operate on amateur radio frequencies, many are research platforms with limited (or no) amateur access. Others send telemetry only. Amateur use is most common on those satellites offering SSB/CW transponders, FM repeaters, and APRS or other digipeater functionality.*

function either as communication relays or research platforms.

Hams have been longing for a high-orbiting "DX" satellite that would relay conversations across entire hemispheres. The last such satellite was OSCAR 40, which became silent in 2004. Unfortunately, it is becoming difficult for non-profit amateur satellite organizations to build such complex, powerful birds while relying solely on member dues and donations, not to mention thousands of hours of volunteer labor. To make matters worse, launch opportunities for large satellites have become increasingly scarce and prohibitively expensive.

# 2 Satellite Transponders

In its most basic form, a *transponder* is the satellite communications system that receives signals from the Earth, alters their frequencies, amplifies them, and sends them back to Earth. The word originates from *transmitter* and *responder*. The transponder is at the heart of every satellite's ability to relay signals. There are three transponder types currently in use.

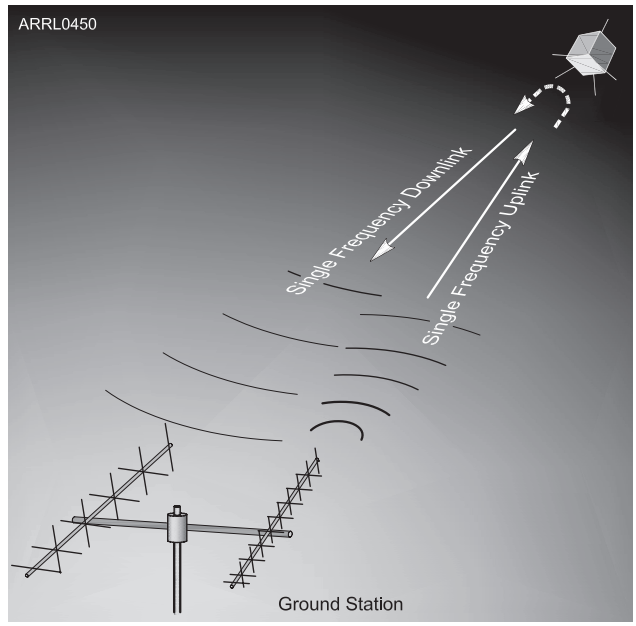

**Figure 1 — A bent-pipe transponder gets its name from the way it functions. It takes the received uplink signal and instantly relays it on the downlink back to its source. Bent-pipe transponders are most often found on satellites that function primarily as FM repeaters.**

## 2.1 "Bent Pipe" Transponders

A bent-pipe transponder is the simplest transponder design in terms of function. It receives a signal at one frequency and simultaneously retransmits it at another. The metaphor is that of a U-shaped pipe that captures an object coming toward it and redirects the object back to its source (**Figure 1**).

A terrestrial FM repeater is a typical example of a bent-pipe transponder. Earthbound repeaters monitor one frequency and retransmit on another, usually (though not always) within the same band. Thanks to their elevated antenna systems, sensitive receivers and considerable output power, terrestrial repeaters can extend the coverage of mobile or handheld FM transceivers over hundreds or even thousands of square miles.

Bent-pipe satellite transponders also function as FM repeaters (although they could just as easily relay other modulation modes such as SSB). Satellite repeaters lack the output power of terrestrial repeaters because power generation in space is a difficult proposition. But what satellite repeaters lack in output power they more than make up for in antenna elevation. Even something as meager as a ¼λ whip antenna can become a transmitting and receiving powerhouse when it is hundreds of miles above the planet.

The principle advantage of a bent-pipe transponder operating in the FM mode is that it is readily compatible with common amateur radio FM transceivers. Satellites such as AMRAD-OSCAR 27 can be easily worked with the same transceivers you'd otherwise use to chat through a local FM repeater. It isn't uncommon to hear mobile and even handheld portable stations communicating through these satellites.

The principle *disadvantage* of a bent-pipe transponder is that it can relay only one signal at a time. Multiple signals on the satellite uplink frequency interfere with each other, usually resulting in an unintelligible cacophony on the downlink. Thanks to the "capture effect" common to FM receivers, only the strongest signal will come through clearly. With only 10 or 15 minutes available during typical low-orbit passes, an inconsiderate operator running high power can use the capture effect to monopolize the satellite, effectively shutting out all other stations.

The solution to the bent-pipe problem is to have a satellite that can relay more than one signal at a time. That requires a completely different sort of transponder.

## 2.2 Linear Transponders

Unlike a bent-pipe transponder that can relay only one signal at a time, a linear transponder receives signals in a narrow slice of the RF spectrum (the *passband*), shifts the frequency of the passband, amplifies all signals linearly, and then retransmits everything back to Earth. Rather than relaying only one signal, a satellite equipped with a linear transponder can relay many signals at once (**Figure 2**).

From an operator point of view, linear transponders have an enormous advantage. With single-channel bent-pipe transponders, the user is obligated to finish a conversation quickly and clear the frequency so that someone else can make a contact. Not so with linear transponders. With the ample spectrum available through a linear transponder, there is more than enough "room" for everyone to communicate for as long as they please, or at least until the satellite travels out of range.

A linear transponder can be used with any type of signal when real time communication is desired. From the standpoint of conserving valuable spacecraft resources such as power and bandwidth, however, the preferred user modes are SSB and CW. Transponders are specified by first giving the approximate input frequency followed by the output frequency. For example, a 146/435-MHz transponder has an input passband centered near 146 MHz and an output passband centered near 435 MHz. The same transponder could be specified in wavelengths, as a 2 meter/70 centimeter unit.

### TRANSPONDER MODES

To keep linear transponder specifications as simple as possible, the satellite community often uses so-called *Mode* designators. In the early years of amateur satellite operation, these designations were rather arbitrarily assigned and bore little resemblance to the actual frequencies in use. Fortunately, the amateur satellite community has since settled on a newer series of transponder specifications that are far more intuitive. For instance, in our previous example, the 2 meter band is tagged with the label "V" (for VHF) while

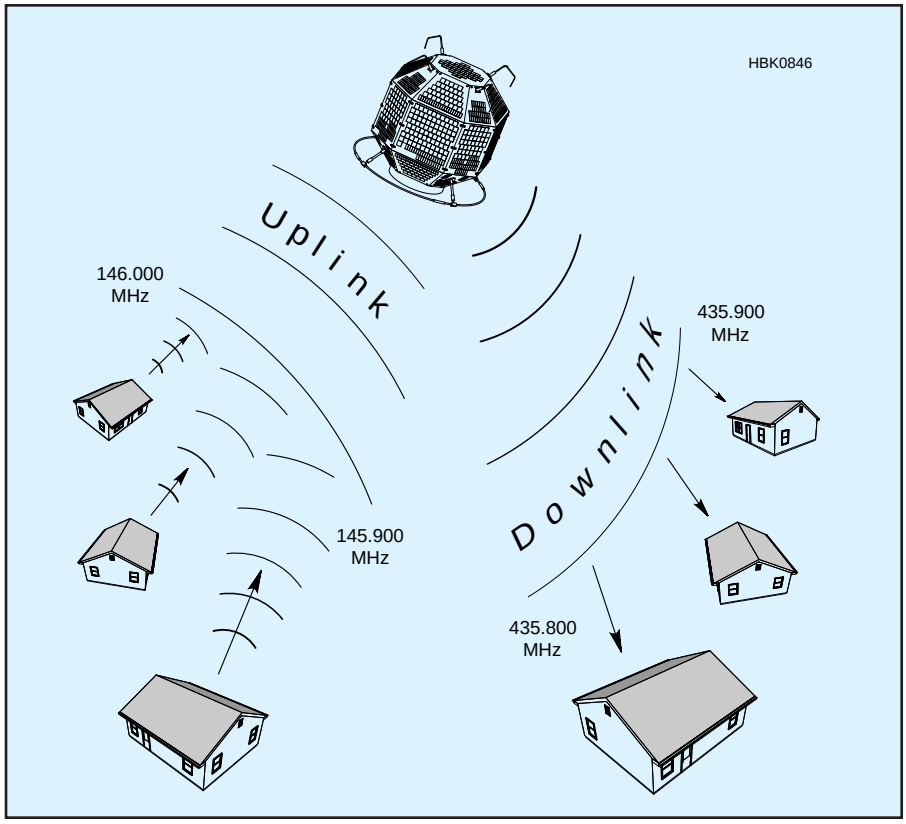

**Figure 2 — Linear transponders repeat all signals received in an entire slice of spectrum. This allows the satellite to relay many conversations simultaneously.**

the 70 centimeter band is labeled "U" (for UHF). Therefore, a transponder that listens on 2 meters and repeats on 70 centimeter is today usually called a Mode V/U transponder. See **Table 2**.

Transponder design is, in many respects, similar to receiver design. Input signals are typically on the order of $10^{-13}$ W and the output level can be up to several watts. A major difference, of course, is that the transponder output is at radio frequency while the receiver output is at audio frequency. A block diagram of a simple transponder is shown in **Figure 3**. For several reasons, flight-model transponders are more complex than the one shown.

In spacecraft applications a key characteristic of a linear amplifier is its overall efficiency (RF output/dc input). Once we reach power levels above a few watts the use of class A, AB or B amplifiers cannot be tolerated. The power and bandwidth of a transponder must be compatible with each other and with the mission. That is, when the transponder is fully loaded with equal-strength signals, each signal should provide an adequate signal-to-noise ratio at the ground. Selecting appropriate values accurately on a theoretical basis using only link calculations is error prone. Experience with a number of satellites, however, has provided AMSAT with a great deal of empirical data from which it's possible to extrapolate accurately to different orbits, bandwidths, power levels, frequencies and antenna characteristics.

In general, low-altitude (300 to 1600 km) satellites that use passive magnetic stabilization and omnidirectional antennas can provide reasonable downlink performance with from 1 to 10 W PEP at frequencies between 29 and 435 MHz, using a 50- to 100-kHz-wide transponder. A high-altitude (35,000 km) spin-stabilized satellite that uses modest (7 to 10 dBi) gain antennas should be able to provide acceptable performance with 35 W PEP using a 300-kHz-wide transponder downlink at 146 or 435 MHz. Transponders are usually configured to be *inverting* in order to minimize Doppler shift. This means, for example, that a signal with a frequency at the low end of the uplink passband shifts to a corresponding point on the high end of the downlink passband. In the case of an SSB signal, the sideband modulation inverts as well — lower sideband on the uplink becomes upper sideband on the downlink.

## DYNAMIC RANGE

The dynamic range problem for transponders is quite different from that for HF receivers. At first glance it may seem that the situation faced by satellite transponders is simpler. After all, an HF receiver must be designed to handle input signals differing in strength by as much as 100 dB, while a low-altitude satellite will encounter signals in its passband differing by perhaps 40 dB. Good HF receivers solve the problem by filtering out all but the desired signal before introducing significant gain. A satellite, however, has to accommodate all users simultaneously. The maximum overall gain can, therefore, be limited by the strongest signal in the passband.

Considering the state-of-the-art in transponder design and available spacecraft power budgets, an effective dynamic range of about 25 dB is about the most that can

**Table 2**
**Satellite Uplink/Downlink Mode Designators**

*Satellite Band Designations*
10 meters (29 MHz): H
2 meters (145 MHz): V
70 centimeters (435 MHz): U
23 centimeters (1260 MHz): L
13 centimeters (2.4 GHz): S
5 centimeters (5.6 GHz): C
3 centimeters (10 GHz): X

*Common Operating Modes (Uplink/Downlink)*
V/H (2 meters/10 meters)
H/V (10 meters/2 meters)
U/V (70 centimeters/2 meters)
V/U (2 meters/70 centimeters)
U/S (70 centimeters /13 centimeters)
U/L (70 centimeters/23 centimeters)
L/S (23 centimeters/13 centimeters)
L/X (23 centimeters/3 centimeters)
C/X (5 centimeters/3 centimeters)

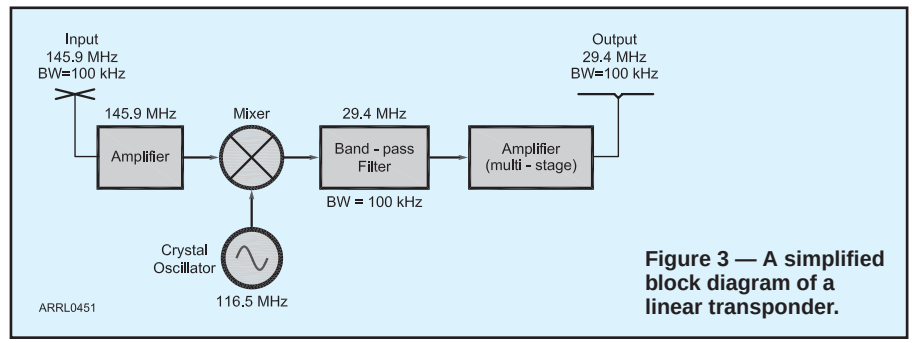

**Figure 3 — A simplified block diagram of a linear transponder.**

be currently obtained. In earlier satellites, the receiver AGC was normally adjusted to accommodate the loudest user. As a result, stations 25 dB weaker were not able to put a usable signal through the spacecraft even though they might be capable of doing so when the AGC is not activated. In the ideal situation users would adjust uplink power so that spacecraft AGC is never activated.

The "power-hog" problem is a serious one. A single station running excessive power can effectively swamp a linear transponder. Far too often, an inexperienced operator may believe that cranking up transmit power will improve downlink signal strength. Instead, that increase in power only serves to depress the downlink signal levels of all other stations.

In the short-lived OSCAR 40 satellite, the designers tried an innovative approach to the power-hog problem with the addition of LEILA (*LEI*stungs *L*imit *A*nzeige [Power Limit Indicator]). LEILA's computer continuously monitored the 10.7 MHz transponder IF passband. When an uplink signal exceeded a predetermined level, the computer inserted a CW message over the offender's downlink. The message indicated to the transmitting station that the transponder was being overloaded, and served as an inducement for the offending station to reduce power until the CW signal disappeared. If the overloading signal continued, or exceeded an even higher preset level, LEILA activated a notch filter tuned to the offending station's frequency. LEILA turned out to be highly effective. If you suddenly heard CW being transmitted over your signal on the downlink, you knew you had to reduce power immediately or face the consequences.

Since the transponder is the primary mission subsystem, reliability is extremely important. One way to improve system reliability is to include at least two transponders on each spacecraft; if one fails, the other would be available full time. And there are significant advantages to *not* using identical units.

## 2.3 Digital Transponders

Digital transponders differ significantly from linear transponders. A digital transponder demodulates the incoming signal. The data can then be stored aboard the spacecraft (as in a packet mailbox) or used to immediately regenerate a digital downlink signal (as in a digipeater). The mailbox service is best suited to low altitude spacecraft. Digipeating is most effective on high altitude spacecraft. Like linear transponders, digital units are downlink limited. A key step in the design procedure is to select modulation techniques and data rates to maximize the downlink capacity. Using assumptions about the type of traffic expected, the designers select appropriate uplink parameters. An analysis suggests that the uplink data capacity should be about four or five times that of the downlink because of "collisions" among signals trying to access the transponder.

For mailbox operation designers often use a PACSAT (*packet radio satellite*) model with similar data rates for the uplink and downlink, and they couple a single downlink with four uplinks. Fuji-OSCARs 12 and 20, and the MicroSat series ran both links at 1200 bps. These PACSATs contained an FM receiver with a demodulator that accepted Manchester-encoded FSK on the uplink. To produce an appropriate uplink signal, ground stations needed FM transmitters and packet radio modems known as terminal node controllers (TNCs) that were capable of generating the Manchester-encoded signal for the uplink.

The PACSAT downlink used binary phase-shift keying (BPSK) at an output of either 1.5 or 4 W. This modulation method was selected because, at a given power level and bit rate, it provides a significantly better bit error rate than other methods that were considered. One way of receiving the downlink is to use an SSB receiver and pass the audio output to a PSK demodulator. The SSB receiver is just serving as a linear downconverter in this situation. Other methods of capturing the downlink are possible but the two proven systems now operating use this approach.

During the heydays of the PACSATs, there were several TNCs designed specifically for this application. Over time the PACSATs have gradually gone out of service and those specialized TNCs have all but disappeared from the marketplace. The remaining digital satellite transponders use 1200 bps AFSK or 9600 bps FSK data transmissions for both uplink and downlink. This means that ordinary packet radio TNCs — the kind currently used for various terrestrial applications — can be used with these digital satellites as well.

### RUDAK

A discussion of digital transponders would not be complete without mentioning RUDAK. RUDAK is an acronym for Regenerativer Umsetzer fur Digitale Amateurfunk Kommunikation (Regenerative Transponder for Digital Amateur Communications). Early RUDAK systems took a different approach to achieving the desired ratio of uplink to downlink capacity. The one flown on OSCAR 13 used one uplink channel and one downlink channel with the data rate on the uplink (2400 bps) roughly six times that on the downlink (400 bps). The 400 bps rate on the downlink was chosen because this was the standard that had been used for downlinking high-orbiting satellite telemetry since the late 1970s. Users already capturing telemetry would be able to capture RUDAK transmissions from day one. Unfortunately, the RUDAK unit on OSCAR 13 failed during launch.

A system known as RUDAK II was flown on RS-14/AO-21 and actually consisted of two units. One unit was similar to the RUDAK flown on OSCAR 13. However, the other unit, known as the RUDAK Technology Experiment (or RTX), was a new experimental transponder using DSP technology. It was essentially a flying test bed for ideas being considered for future high-orbit missions.

The RUDAK-U system flown on OSCAR 40 contained two CPUs, one 153.6 kbaud modem, four hardwired 9600 baud modems and eight DSP modems capable of operating at speeds up to 56 kbaud. The great advantages of modern RUDAK systems are their extraordinary flexibility. Through the use of digital signal processing, the RUDAK is able to configure itself into any type of digital system desired. Had OSCAR 40 survived, the plan was to use its RUDAK system to create a highly capable digital communications platform in space.

# 3 Satellite Tracking

## 3.1 Satellite Orbits

Most active amateur satellites are in various types of low Earth orbits (LEOs) at altitudes that vary between approximately 350 km (the International Space Station) and 1300 km (OSCAR 29). There are satellites planned for future launch that will travel in the high Earth orbits (HEOs). At their closest approaches to Earth (their *perigees*), these satellites may come within 1000 km; at the highest points of their orbits (their *apogees*), they will travel as far as 50,000 km into space. Let's take a brief look at several of the most common orbits.

An *inclined* orbit is one that is inclined with respect to the Earth's equator. See **Figure 4A**. A satellite that is inclined 90° would be orbiting from pole to pole; smaller inclination angles mean that the satellite is spending more time at lower latitudes. The International Space Station, for example, travels in an orbit that is inclined about 50° to the equator. Satellites that move in these orbits frequently fall into the Earth's shadow (eclipse), so they must rely on battery systems

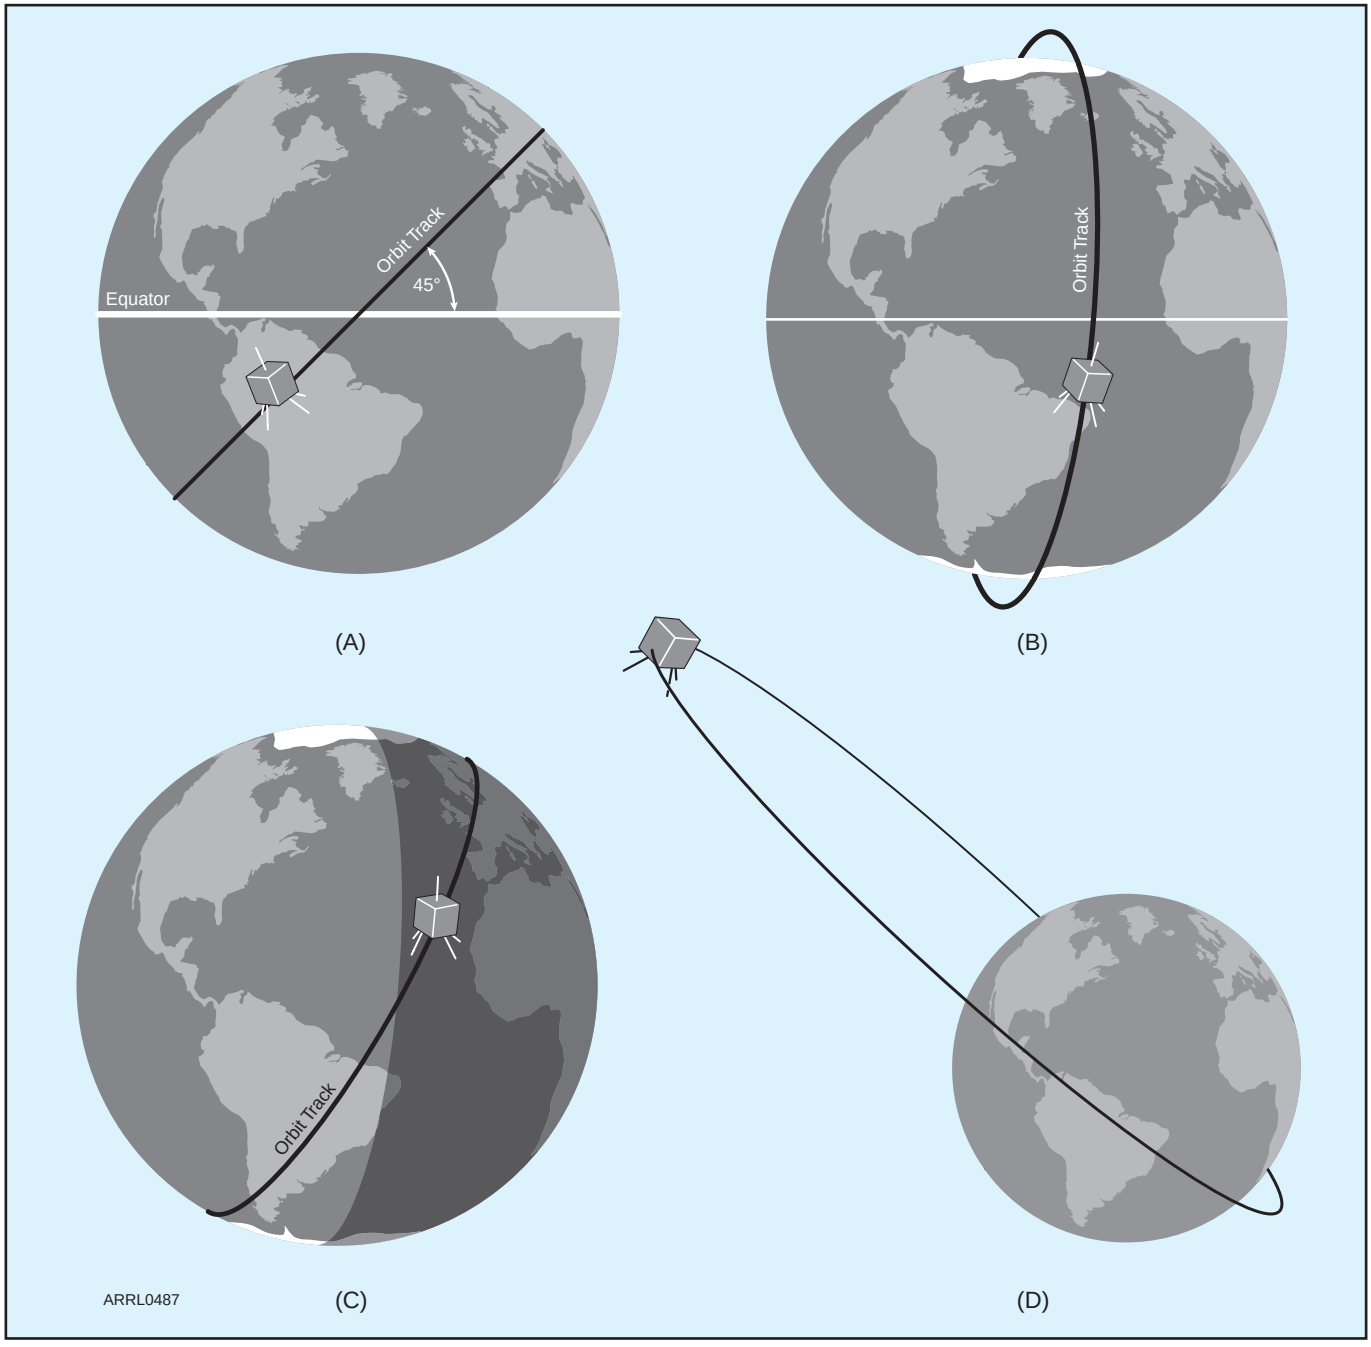

**Figure 4 — At A, an *inclined* orbit is one that is inclined with respect to the Earth's equator (in this case, 45°). At B, a *sun-synchronous* orbit takes the satellite over the north and south poles, allowing every station in the world to enjoy at least one high-elevation pass per day. At C, a *dawn-to-dusk* orbit is a variation on the sun-synchronous model except that the satellite spends most of its time in sunlight and relatively little time in eclipse. At D, the *Molniya* orbit is an elliptical orbit that carries the satellite far into space at its greatest distance from Earth (apogee). To observers on the ground, the satellite at apogee appears to hover for hours at a time before it plunges earthward and (often) sweeps within 1000 km at its closest approach (perigee).**

to provide power when the solar panels are not illuminated. Depending on the inclination angle, some locations on the Earth will never have good access because the satellites will rarely rise above their local horizons. This was true, for example, in the days when the US Space Shuttles carried amateur radio operators. Shuttle orbits were usually inclined at low angles, which meant that Shuttles barely made it above the horizon for hams in the northern US and Canada.

A *sun-synchronous* orbit takes a satellite over the north and south poles. See Figure 4B. There are two advantages to a sun-synchronous orbit: (1) the satellite is available at approximately the same time of day, every day and (2) everyone, no matter where they are, will enjoy at least one high-altitude pass per day. OSCAR 91 is a good example of a satellite that travels in a sun-synchronous orbit.

A *dawn-to-dusk* orbit is a variation on the sun-synchronous model except that the satellite spends most of its time in sunlight and relatively little time in shadow. OSCAR 27 travels in a dawn-to-dusk orbit. See Figure 4C.

The *Molniya* high Earth orbit (Figure 4D) was pioneered by the former Soviet Union. It is an elliptical orbit that carries the satellite far into space at its greatest distance from Earth. To observers on the ground, the satellite at apogee appears to hover for hours at a time before it plunges earthward and sweeps around the Earth at its closest approach. One great advantage of the Molniya orbit is that the satellite is capable of "seeing" an entire hemisphere of the planet while at apogee. Hams can use a Molniya satellite to enjoy long, leisurely conversations spanning thousands of kilometers here on Earth. When this book was written, however, there were no active ham satellites traveling in Molniya orbits.

## 3.2 Satellite Tracking Software

The key to communicating through a satellite is being able to track its movements and predict when it will appear above your local horizon. Fortunately, we have sophisticated software available that streamlines this task considerably.

You'll find satellite-tracking software written for Windows, macOS and Linux operating systems. Several popular applications are listed in **Table 3**. When computers were first employed to track amateur satellites, they provided only the most basic, essential information: when the satellite will be available (*AOS*, acquisition of signal), how high the satellite will rise in the sky and when the satellite is due to set below your horizon (*LOS*, loss of signal). Today we tend to ask a great deal more of our tracking programs. Modern applications still provide the basic information, but they usually offer many more features such as:

- The spacecraft's operating schedule, including which transponders and beacons are on.
- Predicted frequency offset (Doppler shift) on the link frequencies.
- The orientation of the spacecraft's antennas with respect to your ground station and the distance between your ground station and the satellite.
- Which regions of the Earth have access to the spacecraft; that is, who's in QSO range?
- Whether the satellite is in sunlight or being eclipsed by the Earth. Some spacecraft only operate when in sunlight.
- When the next opportunity to cover a selected terrestrial path (mutual window) will occur.
- Changing data can often be updated at various intervals such as once per minute — or even once per second.

A number of applications do even more. Some will control antenna rotators, automatically keeping directional antennas aimed at the target satellite. Other applications will also control the radio to automatically compensate for frequency changes caused by Doppler shifting.

Adding additional spacecraft to the scenario suggests more questions. Which satellites are currently in range? How long each will be accessible? Will any new spacecraft be coming into range in the near future? Obviously there is a great deal of information of potential interest. Programmers developing tracking software often find that the real challenge is not solving the underlying physics problems, but deciding what information to include and how to present it in a useful format. This is especially true since users have different interests, levels of expertise and needs. Some prefer to see the information in a graphical format, such as a map showing real-time positions for all satellites of interest. Others may prefer tabular data such as a listing of the times a particular spacecraft will be in range over the next several days.

There are also several internet sites where you can do your tracking online. This eliminates all the hassles associated with acquiring and installing software. The currently available online tracking sites are not as powerful or flexible as the software you can install on your PC, however. One interesting site of this type is maintained by AMSAT-NA and you'll find it at **www.amsat.org/track/**.

## 3.3 Getting Started With Software

There are so many different types of satellite software, and they change so frequently, it would be foolhardy to attempt to give you detailed operational descriptions in any book. The book would be obsolete a month after it came off the press!

Even so, there are a number of aspects of satellite-tracking software that rarely change. For instance, most programs will ask you to enter your station location as part of the initial setup process. Some applications use the term "observer" to mean "station location," but the terms are synonymous for the sake of our discussion. Sophisticated programs will go as far as to provide you with a list of cities that you can select to quickly enter your location. Other programs will ask you to enter your latitude and longitude coordinates manually.

When entering latitude, longitude (and other angles), make sure you know whether the computer expects degree-minute or decimal-degree notation. Following the notation used

**Table 3**
**A Sampling of Satellite Tracking Software**

| *Name* | *Source* | *Operating System* | *Radio Control?* | *Antenna Control?* |
|---|---|---|---|---|
| *Nova* | **www.amsat.org** (store) | Windows | No | Yes |
| *SCRAP* | **www.amsat.org** (store) | Windows | No | Yes |
| *SatPC32* | **www.amsat.org** (store) | Windows | Yes | Yes |
| *SatScape* | **www.satscape.co.uk/classic.html** | Windows | Yes | Yes |
| *MacDoppler* | **www.dogparksoftware.com/MacDoppler.html** | macOS | Yes | Yes |
| *Ham Radio Deluxe* | **hrd.ham-radio.ch** | Windows | Yes | No |
| *Predict* | **www.qsl.net/kd2bd/predict.html** | Linux | No | Yes |
| *WinOrbit* | **www.sat-net.com/winorbit** | Windows | No | No |

by the on-screen prompt usually works. Also make sure you understand the units and sign conventions being used. For example, longitudes may be specified in negative number for locations west of Greenwich (0° longitude). Latitudes in the southern hemisphere may also require a minus sign. Fractional parts of a degree will have very little effect on tracking data so in most cases you can just ignore it.

Dates can also cause considerable trouble. Does the day or month appear first? Can November be abbreviated Nov or must you enter 11? The number is almost always required. Must you write 2010 or will 10 suffice? Should the parts be separated by colons, dashes or slashes? The list goes on and on. Once again, the prompt is your most important clue. For example, if the prompt reads "Enter date (DD:MM:YY)" and you want to enter February 9, 2010 follow the format of the prompt as precisely as possible and write 09:02:10.

When entering numbers, commas should never be used. For example, if a semi-major axis of 20,243.51 km must be entered, type 20243.51 with the comma and units omitted. It takes a little time to get used to the quirks of each software package, but you'll soon find yourself responding automatically.

Once you have your coordinates entered, you're still not quite done. The software now "knows" its location, but it doesn't know the locations of the satellites you wish to track. The only way the software can calculate the positions of satellites is if it has a recent set of *orbital elements*.

## 3.4 Orbital Elements

Orbital elements are sets of six numbers that completely describe the orbit of a satellite at a specific time. Although scientists may occasionally use different groups of six quantities, radio amateurs nearly always use the six known as Keplerian Orbital Elements, or simply *Keps*.

These orbital elements are derived from very precise observations of each satellite's orbital motion. Using precision radar and highly sensitive optical observation techniques, the North American Aerospace Defense Command (NORAD) keeps a very accurate catalog of almost everything in Earth orbit. Periodically, they issue the unclassified portions of this information to the National Aeronautics and Space Administration (NASA) for release to the general public. The information is listed by individual catalog number of each satellite and contains numeric data that describes, in a mathematical way, how NORAD observed the satellite moving around the Earth at a very precise location in space at a very precise moment in the past.

Without getting into the complex details of orbital mechanics, suffice it to say that your software simply uses the orbital element information NASA publishes that describe where a particular satellite was "then" to solve the orbital math and make a prediction (either graphically or in tabular format) of where that satellite ought to be "now." The "now" part of the prediction is based on the local time and station location information you've also been asked to load into your software.

Orbital elements are frequently distributed with additional numerical data (which may or may not be used by a software tracking program) and are commonly available in two forms, NASA format and AMSAT format.

**Table 4**

### UNDERSTANDING THE AMSAT FORMAT

Let's use the easier-to-understand AMSAT format example shown in **Table 4** to break down the meaning, line by line.

The first two entries identify the spacecraft. The first line is an informal *satellite name*. The second entry, *Catalog Number*, is a formal ID assigned by NASA.

The next entry, *Epoch Time*, specifies the time the orbital elements were computed. The number consists of two parts, the part to the left of the decimal point that describes the year and day, and the part to the right of the decimal point that describes the (very precise) time of day. For example, 96325.465598 refers to 1996, day 325, time of day .465598.

The next entry, *Element Set*, is a reference used to identify the source of the information. For example, 199 indicates element set number 199 issued by AMSAT. This information is optional.

The next six entries are the six key orbital elements.

*Inclination* describes the orientation of the satellite's orbital plane with respect to the equatorial plane of the Earth.

*RAAN, Right Ascension of Ascending Node*, specifies the orientation of the satellite's orbital plane with respect to fixed stars.

*Eccentricity* refers to the shape of the orbital ellipse. The closer this number is to 0, the more circular the orbit of the satellite tends to be. Conversely, an eccentricity value approaching 1 indicates the satellite is following a more elliptically shaped orbital path.

*Argument of Perigee* describes where the perigee of the satellite is located in the satellite orbital plane. Recall that a satellite's perigee is its closest approach to the Earth. When the argument of perigee is between 180 and 360° the perigee will be over the Southern Hemisphere. Apogee — a satellite's most distant point from the Earth — will therefore occur above the Northern Hemisphere.

*Mean Anomaly* locates the satellite in the orbital plane at the epoch. All programs use the astronomical convention for mean anomaly (MA) units. The mean anomaly is 0 at perigee and 180 at apogee. Values between 0 and 180 indicate that the satellite is headed up toward apogee. Values between 180 and 360 indicate that the satellite is headed down toward perigee.

*Mean Motion* specifies the number of revolutions the satellite makes each day. This element indirectly provides information about the size of the elliptical orbit.

*Decay Rate* is a parameter used in sophisticated tracking models to take into account how the frictional drag produced by the Earth's atmosphere affects a satellite's orbit. It may also be referred to as rate of change of mean motion, first derivative of mean motion, or drag factor. Although decay rate is an important parameter in scientific studies of the Earth's atmosphere and when observing satellites that are about to reenter, it has very little effect on day-to-day tracking of most amateur radio satellites. If your program asks for drag factor, enter the number provided. If the element set does not contain this information enter zero — you shouldn't discern any difference in predictions. You usually have a choice of entering this number using either decimal form or scientific notation. For example, the number –0.00000039 (decimal form) can be entered as –3.9e–7 (scientific notation). The e–7 stands for 10 to the minus seventh power (or $10^{-7}$). In practical terms e–7 just means move the decimal in the preceding number 7 places to the left. If this is totally confusing, just remember that in most situations entering zero will work fine.

*Epoch revolution* is just another term for the expression "Orbit Number" that we discussed earlier. The number provided here does not affect tracking data, so don't worry if different element sets provide different numbers for the same day and time.

The *Checksum* is a number constructed by the data transmitting station and used by the receiving station to check for certain types of transmission errors in data files. It does not bear any relationship to a satellite's orbit.

In the "old days" of satellite-tracking software you had to enter the orbital elements by hand. This was a tedious and risky process. If you entered an element number incorrectly, you would generate wildly inaccurate predictions.

Today, thankfully, most satellite-tracking programs have greatly streamlined the process. One method of entering orbital elements is to grab the latest set from the AMSAT-NA website at **www.amsat.org** (look under "Keps" in the main menu). You can download the element set as a text file and then tell your satellite-tracking program to read the file and create the database. Another excellent site is CelesTrak at **celestrak.com**. Your program will probably be able to read either the AMSAT or NASA formats.

If you're fortunate to own sophisticated tracking software such as *Nova*, and you have access to the internet, the program will reach into cyberspace, download and process its Keps automatically. All it takes is a single click of your mouse button. Some programs can even be configured to download the latest Keps on a regular basis without any prompting from you.

## 3.5 Other Tracking Considerations

### SATELLITE FOOTPRINTS

Many satellite tracking applications display not only the satellite track, but also the satellite *footprint*. A satellite footprint can be loosely defined as the area on the Earth's surface that is "illuminated" by the satellite's antenna systems at any given time. Another way to think of a footprint is to regard it as the zone within which stations can communicate with each other through the satellite.

Unless the satellite in question is *geostationary*, footprints are constantly moving. Their sizes can vary considerably, depending on the altitude of the satellite. The footprint of the low-orbiting International Space Station is about 600 km in diameter. In contrast, the higher orbiting OSCAR 52 has a footprint that is nearly 1500 km across. See the example of a satellite footprint in **Figure 5**. The amount of time you have available to communicate depends on how long your station remains within the footprint. This time can be measured in minutes, or in the case of a satellite in a highly elliptical orbit, hours.

It is worthwhile to note that the size and even the shape of a footprint can also vary according to the type of antenna the satellite is using. A highly directional antenna with a narrow beamwidth will create a small footprint even though the satellite is traveling in a high-altitude orbit. This usually isn't an issue for amateur satellites, however.

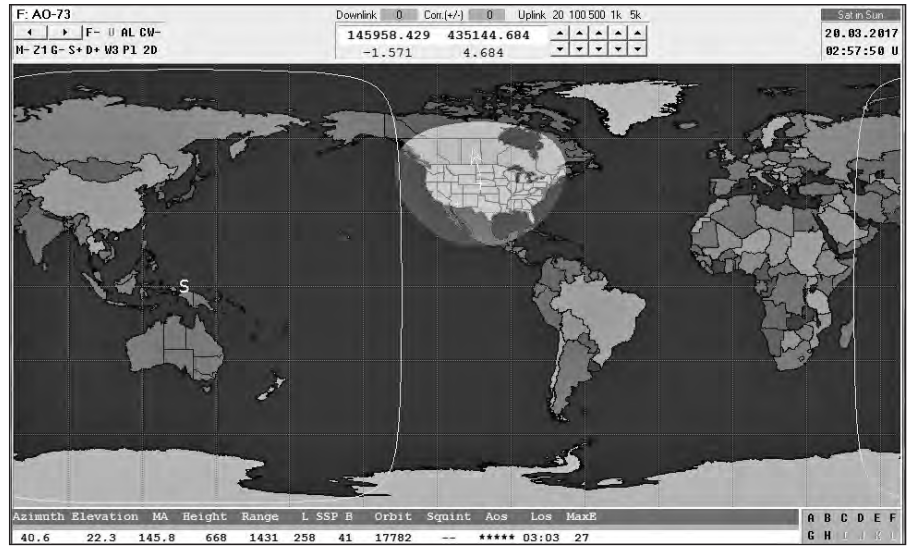

**Figure 5 — This image shows the circular footprint as depicted by *NOVA* satellite-tracking software. The footprint indicates the area of the Earth that is visible to the satellite at any given time.**

### A SATELLITE'S "PHASE"

Some satellites use operating schedules to determine which transponders and antennas are active at any given time. It is based on the *phase* of the satellite's *mean anomaly*, or *MA*. Many software applications can use this information to provide detailed predictions that tell you not only when the satellite will appear, but also which transponders will be active at the time.

The expression "anomaly" is just a fancy term for *angle*. Astronomers have traditionally divided orbits into 360 mean-anomaly units, each containing an equal time segment. Because of the architecture of common microprocessors, it was much more efficient to design the computers controlling spacecraft to divide each orbit into 256 segments of equal time duration. Radio amateurs refer to these as mean anomaly or phase units. The duration of each segment is the satellites period divided by 256. For example, a mean anomaly unit for OSCAR 13 was roughly 2.68 minutes. At MA 0 (beginning of orbit) and MA 256 (end of orbit) the satellite is at perigee (its lowest point). At MA 128 (halfway through the orbit) the satellite is at apogee or high point. See **Figure 6**.

Because radio amateurs and astronomers use the term mean anomaly in a slightly different way, there's sometimes a question as to which system is being used. Any confusion is minor and usually easily resolved. Most OSCAR telemetry with real-time MA values and schedules use the 256 system. The term "phase" — and the fact that no numbers larger than 256 ever appear — are significant hints. Computer tracking programs designed for non-radio amateur audiences generally use the traditional astronomical notation. It's easy to determine when this is the case because the mean anomaly column will contain entries between 257 and 360.

If a satellite is using an MA-based transponder schedule, the schedule will be posted on the AMSAT-NA website at **www.amsat.org**. (When this book was written there were no amateur radio satellites in orbit using MA scheduling, but this may change as currently planned satellites reach orbit.) Depending on its sophistication, your tracking software may allow you to enter this schedule data.

Schedules are generally modified every few months when satellite orientation is adjusted to compensate for changes in the sun angle on the spacecraft. A typical schedule used for OSCAR 13, with its corresponding uplink (transmitting) and downlink (receiving) frequency band requirements, looked like this:

Off: from MA 0 until MA 49

Mode U/V (uplink on 70 centimeters/downlink on 2 meters): on from MA 50 until MA 128

Mode U/S (uplink on 70 centimeters/downlink on 2.4 GHz): on from MA 129 until MA 159

Mode U/V (uplink on 70 centimeters/downlink on 2 meters): on from MA 160 until MA 255

If you wanted to operate Mode U/S, you needed to be at the radio when the satellite was between MA129 and MA159 in its orbit.

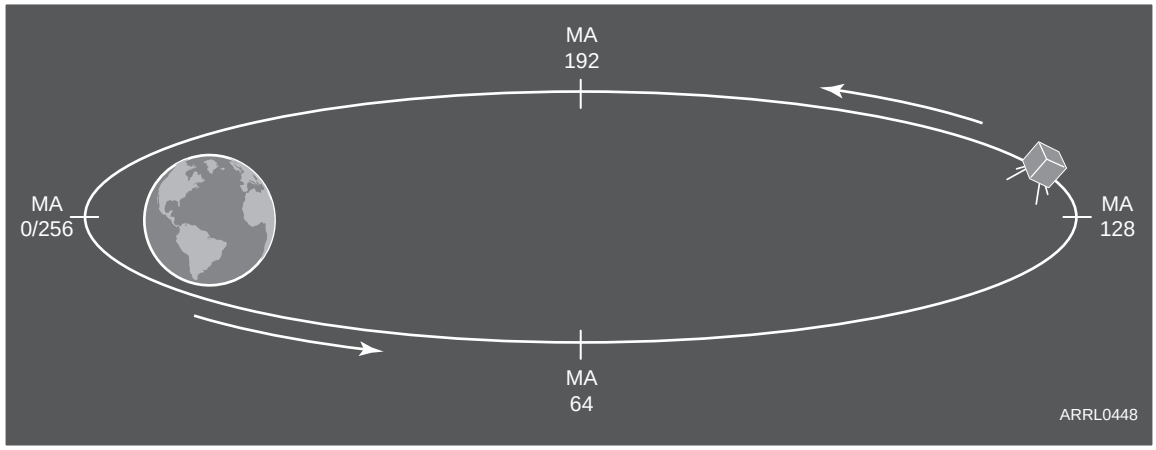

**Figure 6 — Mean anomaly (MA) divides each orbit into 256 segments of equal time duration. Radio amateurs refer to these as "Mean Anomaly" or "Phase" units. The duration of each segment is the satellite's period divided by 256. For example, a mean anomaly unit for OSCAR 13 was roughly 2.68 minutes. At MA 0 (beginning of orbit) and MA 256 (end of orbit) the satellite is at perigee (its lowest point). At MA 128 (halfway through the orbit) the satellite is at apogee (or its highest point).**

## SQUINT ANGLE

Another dilemma your software may help resolve is the *squint angle*. The squint angle describes how the directive antennas on a satellite are pointed with respect to your ground station. Squint angle can vary between 0° and 180°. A squint angle of 0° means the satellite antennas are pointed directly at you and that generally indicates that good link performance can be expected (**Figure 7**). When the squint angle is above 20°, signal level begins to drop and a disruptive amplitude flutter called spin modulation on uplinks and downlinks may become apparent.

Programs that include algorithms to calculate squint angle require information about the orientation or attitude of the satellite. This information is generally available from sources that provide the basic orbital elements and on telemetry sent directly from the satellite of interest. The parameters needed are labeled Bahn latitude and Bahn longitude. They are also known as BLAT and BLON or ALAT and ALON where the prefix "A" stands for attitude.

Programs that provide squint angle information may also contain a column labeled *Predicted Signal Level*. Values are usually computed using a simple prediction model that takes into account satellite antenna pattern, squint angle and spacecraft range. The model assumes a 0 dB reference point with the satellite overhead, at apogee and pointing directly at you. At any point on the orbit the predicted level may be several dB above (+) or below (–) this reference level.

You won't need to be concerned about squint angle for most LEO satellites. It only becomes a factor with the high-orbit birds since they generally use directive antennas. As with MA scheduling, you'll want to know that the satellite's antennas are pointing at your location before you fire up your equipment. With the right kind of software, you'll know well ahead of time.

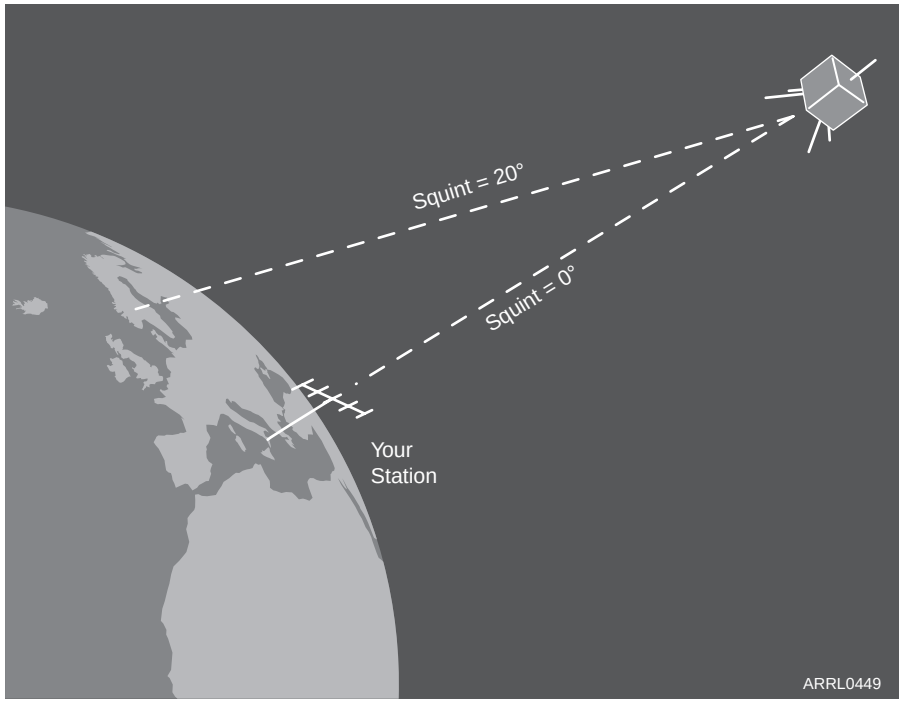

**Figure 7 — The squint angle describes how the directive antennas on a satellite are pointed with respect to your ground station. Squint angles can vary between 0° and 180°. A squint angle of 0° means the satellite antennas are pointed directly at you, which, in turn, means good link performance can usually be expected. When the squint angle is above 20° signal level begins to drop.**

# 4 Satellite Ground Station Antennas

Assembling a satellite ground station presents a different challenge compared to typical HF station setups. There are a number of variables that change depending on the types of satellites you hope to use. A ground station designed strictly for LEO satellites differs substantially from one intended for HEO birds. There are also issues surrounding computers and software, particularly if you plan to access digital satellites.

One aspect of your ground station with the greatest range of choice is your antenna system. To use most amateur satellites, you must transmit on one band (the uplink) and receive on another band (the downlink). Unless you are using a single, dual-band antenna, your satellite station will require at least two antennas. Some satellite operators have several antennas so that they can operate on various uplink/downlink band combinations as the need arises.

## 4.1 Antenna Polarization

The *polarization* of a satellite antenna is an important factor, regardless of whether it is used for transmitting or receiving. Polarization is determined by the position of the radiating element or wire with respect to the Earth. A radiator that is parallel to the Earth radiates horizontally, while a vertical radiator radiates a vertical wave. These are so-called *linearly polarized* antennas. If the radiating element is slanted above the Earth, it radiates waves that have *both* vertical and horizontal components.

For terrestrial VHF+ line-of-sight communication, polarization matching is important. If one station is using a horizontally polarized antenna and the other is using a vertically polarized antenna, the mismatch can result in a large signal loss under certain conditions. We don't worry about polarization mismatches on HF frequencies because whenever signals are refracted through the ionosphere, as HF signals usually are, polarization changes anyway.

The problem with applying polarization concerns to spacecraft is that the orientation of a satellite's antennas relative to your ground station is constantly changing. This often results in fading when the polarization of its antennas conflict with yours. This problem doesn't plague satellites exclusively. Aircraft, automobiles and all other moving radio platforms can suffer the same effects.

Fortunately, there is a "cure" known as *circular polarization* (CP). With CP, wave fronts appear to rotate as they pass the receiving station, either clockwise (right-hand or RHCP) or counter clockwise (left-hand or LHCP). See **Figure 8**. The advantage of using circular polarization is that it can substantially reduce the effects of polarization conflict. Since the polarization of a CP antenna rotates through horizontal and vertical planes, the resulting pattern effectively "smoothes" the fading effects, generating consistent signals as a result.

That said, your satellite ground station antennas do *not* need to be circularly polarized to be effective. Linearly polarized antennas, either horizontal or vertical, are perfectly useful. Some ground station antenna designs use slanted or "crossed" elements to mix the horizontal and vertical polarization components as discussed earlier. The goal of fine-tuning your antenna polarization is to give your station an edge, something that is important when you are dealing with weak signals from deep space. But, while circular polarization of your antennas may give your station a definite advantage, it isn't an absolute requirement.

## 4.2 Omnidirectional Antennas

An ideal omnidirectional antenna radiates and receives signals in all directions equally. In the real world, most "omnidirectional" antennas have a certain amount of directivity. For example, a common ground plane antenna (**Figure 9**) is considered to be omnidirectional, but as you can see in **Figure 10** the

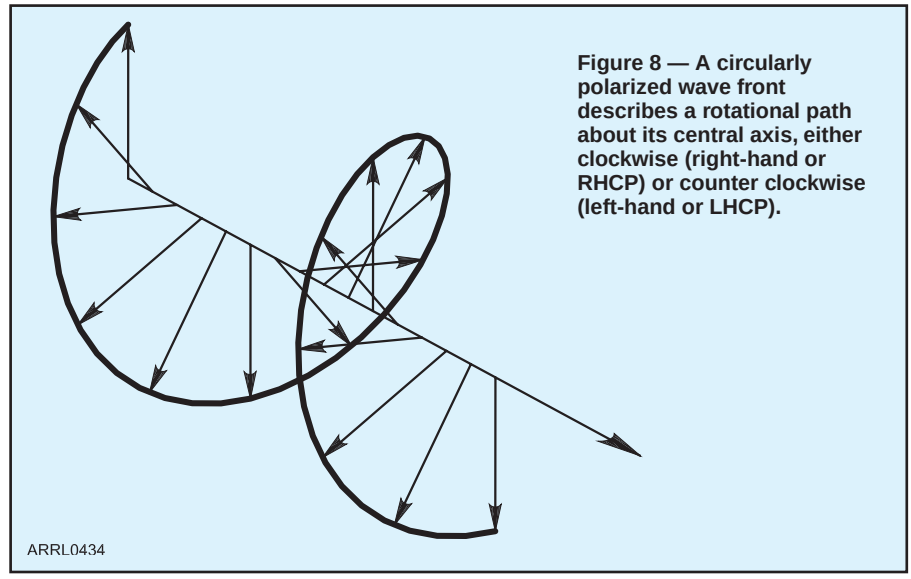

**Figure 8 — A circularly polarized wave front describes a rotational path about its central axis, either clockwise (right-hand or RHCP) or counter clockwise (left-hand or LHCP).**

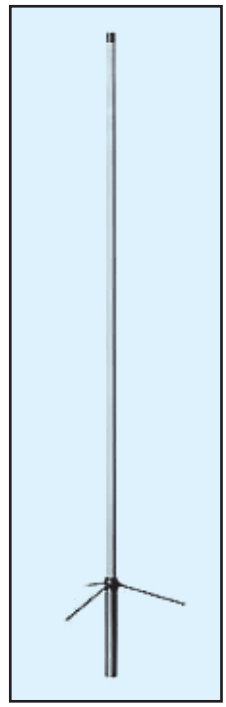

**Figure 9 — An ordinary ground plane antenna. This particular model is designed for terrestrial communications on 2 meters.**

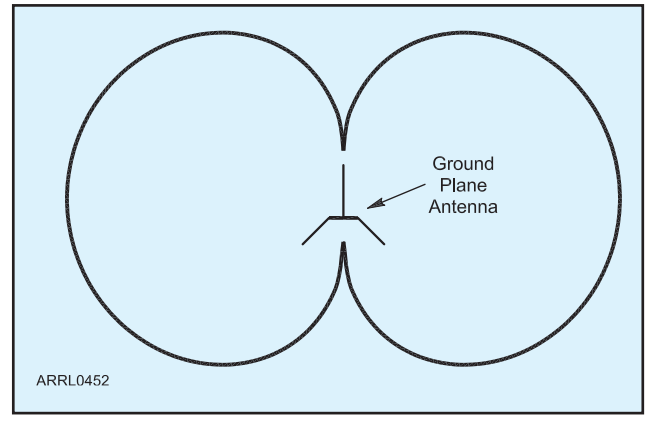

**Figure 10 — The simplified radiation pattern of a ground plane antenna. Notice the deep null directly overhead.**

radiation pattern is not uniform. Notice the deep null directly overhead. Signals will fade sharply as satellites move through this null, particularly during high-elevation passes.

Despite their low gain, omnidirectional antennas are attractive because they do not need to be aimed at their targets. This means that they don't require mechanical antenna rotators, which can add significant cost and complexity to a ground station. Omni antennas are also more compact than directional antennas for the same frequency. On the other hand, their low gain makes them practical only for LEO satellites that have sensitive receivers and relatively strong transmit signals.

Technically speaking, any type of omnidirectional antenna can be used for a satellite ground station. Hams have enjoyed satellite operations with simple ground planes, J-poles, "big wheels" and even automobile antennas. But for best results with an omni-based antenna system, you'll want a radiation pattern that minimizes the polarization conflicts and pattern nulls that can cause signals to fade. To this end, engineers have designed a number of omnidirectional antennas with these issues in mind.

## THE EGGBEATER

The *eggbeater* antenna is a popular design named after the old-fashioned kitchen utensil it resembles (**Figure 11**). The antenna is composed of two full-wave loops of rigid wire or metal tubing. Each of the two loops has an impedance of 100 Ω, and when coupled in parallel they offer an ideal 50 Ω impedance for coaxial feed lines. The loops are fed 90° out of phase with each other and this creates a circularly polarized pattern.

An eggbeater may also use one or more parasitic reflector elements beneath the loops to focus more of the radiation pattern upward. This effect makes it a "gain" antenna, but that gain is at the expense of low-elevation reception. Toward the horizon an eggbeater is actually horizontally polarized. As the pattern rises in elevation, it becomes more and more right-hand circularly polarized. Experience has shown that eggbeaters seem to perform best when reflector elements are installed just below the loops.

Eggbeaters can be built relatively easily, but there are also a couple of commercial models available. The spherical shape of the eggbeater creates a fairly compact antenna when space is an issue, which is another reason why it is an attractive design.

## THE TURNSTILE

The basic *turnstile* antenna consists of two horizontal half-wave dipoles mounted at right angles to each other (like the letter "X") in the same horizontal plane with a reflector screen beneath (**Figure 12**). When these two antennas are excited with equal currents 90° out of phase, their typical figure-eight patterns merge to produce a nearly circular pattern.

In order to get the radiation pattern in the upward direction for space communications, the turnstile antenna needs a reflector underneath. For a broad pattern it is best to maintain a distance of ⅜ λ at the operating frequency between the reflector and the turnstile. Home-brewed turnstile reflectors often use metal window-screen material that you can pick up at many hardware stores. (Make sure it is a metal, not plastic, screen material.)

Like their cousins the eggbeaters, turnstiles are relatively easy to build. In fact, building one may be your only choice since turnstiles are rarely available off the shelf.

## THE LINDENBLAD ANTENNA

In a *Lindenblad* antenna (**Figure 13**), each dipole element is attached to a section of shorted open-wire-line, also made from tubing, which serves as a balun transformer. A coaxial cable runs through one side of each open-wire line to feed each dipole. The four coaxial feed cables meet at a center hub section where they are connected in parallel to provide a four-way, in-phase power-splitting function. This cable junction is connected to another section of coaxial cable that serves as an impedance matching section to get a good match to 50 Ω. An innovative solution, the EZ-Lindenblad, is described later in this chapter. While certainly more elaborate than an eggbeater or turnstile, the Lindenblad creates a uniform circularly polarized pattern that is highly effective for satellite applications.

## THE QUADRIFILAR HELICOIDAL ANTENNA

The quadrifilar helicoidal antenna (QHA) shown in **Figure 14** ranks among the best of the omnidirectional satellite antennas. It is comprised of four equal-length conductors (filars) wound in the form of a corkscrew (helix) and fed in quadrature. The result is a nearly perfect circularly polarized pattern.

QHAs can be challenging to build since the filar lengths and spacing have to be precise. Even so, homebrewing a QHA can save you a substantial amount of money. This antenna is available off the shelf (they are favorites

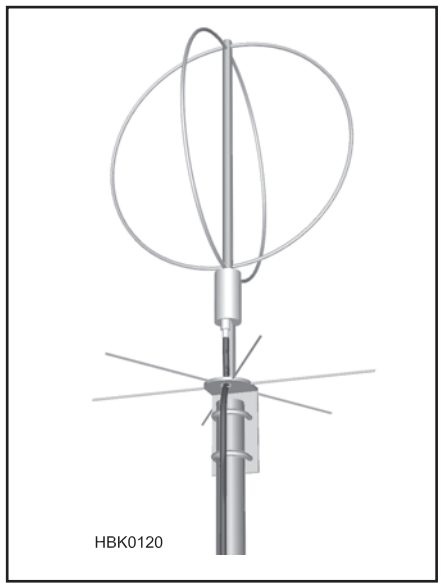

**Figure 11 — The eggbeater antenna is a popular design named after the old-fashioned kitchen utensil it resembles. The antenna is composed of two full-wave loops of rigid wire or metal tubing.**

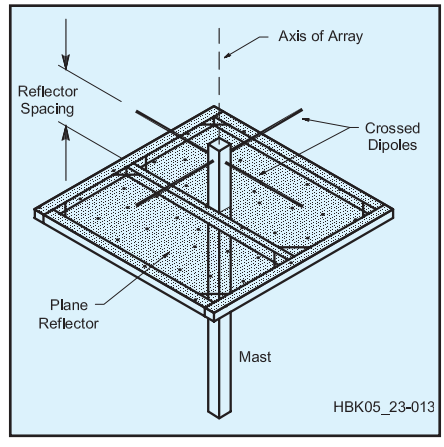

**Figure 12 — The basic turnstile antenna consists of two horizontal half-wave dipoles mounted at right angles to each other (like the letter "X") in the same horizontal plane with a reflector screen beneath.**

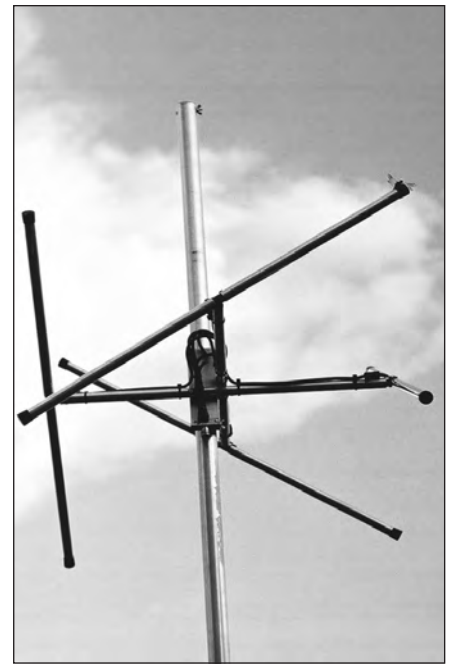

**Figure 13 — The EZ Lindenblad antenna designed by Anthony Monteiro, AA2TX.**

for maritime satellite links), but they can be costly. A version that can be built from readily available materials is described later in this chapter.

## 4.3 Directional Antennas

Gain and directivity are important antenna factors. These factors are maximized in *directional* antennas. In fact, the design goal of a directional antenna is to create a highly directional pattern along its axis (**Figure 15**). An ordinary flashlight is a reasonable analog for a directional antenna, although the pattern of a directional antenna isn't as well focused as a flashlight beam (antennas with parabolic reflectors come fairly close, though).

The chief advantage of a directional antenna is its considerable directivity and gain. When you are working with weak signals from spacecraft, you need all the gain you can get. Directional antennas are mandatory for high-altitude satellites when they are at apogee, nearly 50,000 km distant. They also are excellent for LEO birds, providing strong, consistent signals that omnidirectional antennas can rarely match.

But, a major disadvantage of a directional antenna is *also* its directivity! To achieve best results with a directional antenna, you must find a way to point it at the satellite you wish to work. This entails pointing it by hand, or by using an antenna rotator. If you were to simply leave a directional antenna fixed in one place, you would enjoy good signals only during the brief moments when satellites passed through the antenna's pattern. A rotator adds significant cost to a ground station and installing one isn't a trivial exercise. On the other hand, there is a way to reduce rotator cost, which we'll discuss later.

If you can afford a directional antenna and rotator system, you'll never regret the investment. When properly installed, it is vastly superior to any omnidirectional antenna you are likely to encounter.

### YAGI ANTENNAS

The familiar Yagi antennas used for VHF+ terrestrial operation can be used for satellite applications as well. However, keep in mind that the greater the directivity, the more focused (narrow) the antenna pattern. This translates to an antenna that must be aimed at a satellite with a fair degree of accuracy. This can be a challenge when your target is a rapidly moving LEO bird.

The Yagi antennas you normally see are *linear* designs that are mounted in either horizontal or vertically polarized configurations. These same antennas can be successfully used for satellite work just as they are. However, there are ways you can optimize them to increase their effective performance.

The dipole elements of Yagi antennas radiate linearly polarized signals, but remember that the polarization direction really depends on the orientation of the antenna to the Earth. If two Yagi antennas are mounted on the same support boom, arranged for horizontal and vertical polarization, and combined with the correct phase difference (90°), a circularly polarized wave results. Because the electric fields of the antennas are identical in magnitude, the power from the transmitter will be equally divided between the two fields. Another way of looking at this is to consider the power as being divided between the two antennas; hence

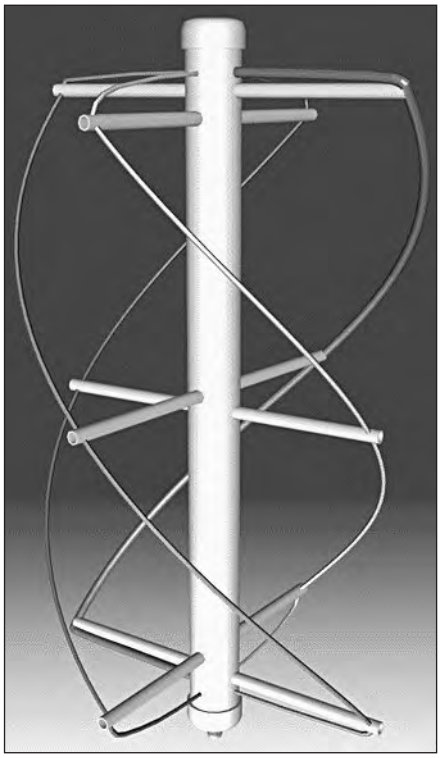

**Figure 14 — The quadrifilar helicoidal antenna is comprised of four equal-length conductors (filars) wound in the form of a corkscrew (helix) and fed in quadrature.**

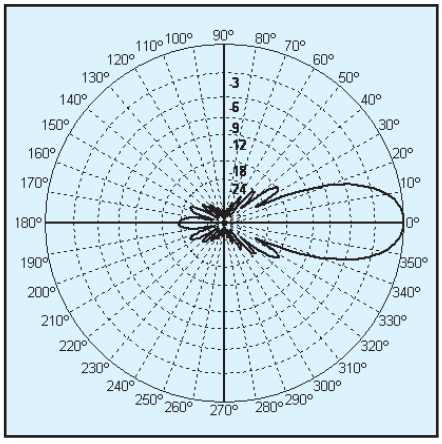

**Figure 15 — The design goal of a directional antenna is to create a highly directional pattern along its axis. This example shows the radiation pattern of a high-gain Yagi antenna.**

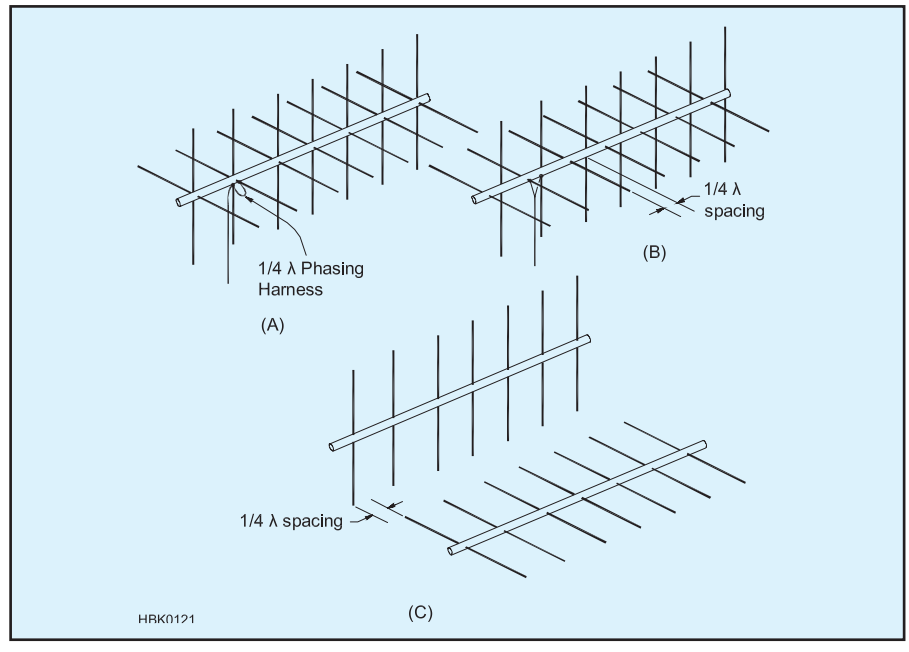

**Figure 16 — Evolution of the circularly polarized Yagi. The simplest form of crossed Yagi, A, is made to radiate circularly by feeding the two driven elements 90° out of phase. Antenna B has the driven elements fed in phase, but has the elements of one bay mounted ¼ λ forward from those of the other. Antenna C offers elliptical (circular) polarization using separate booms. The elements in one set are mounted perpendicular to those of the other and are spaced ¼ λ forward from those of the other.**

the gain of each is decreased by 3 dB when taken alone in the plane of its orientation. This design is known as a *crossed Yagi*.

A 90° phase shift must exist between the two antennas and the simplest way to obtain this shift is to use two feed lines. One feedline section is ¼ λ longer than the other, as shown in **Figure 16**. These separate feed lines are then paralleled to a common transmission line to the station. However, therein lies one of the headaches of this system. Assuming negligible coupling between the crossed antennas, the impedance presented to the common transmission line by the parallel combination is one half that of either section alone. (This is not true when there is mutual coupling between the antennas, as in phased arrays.) **Figure 17** shows a practical example of offset crossed Yagis for the 23 centimeter band.

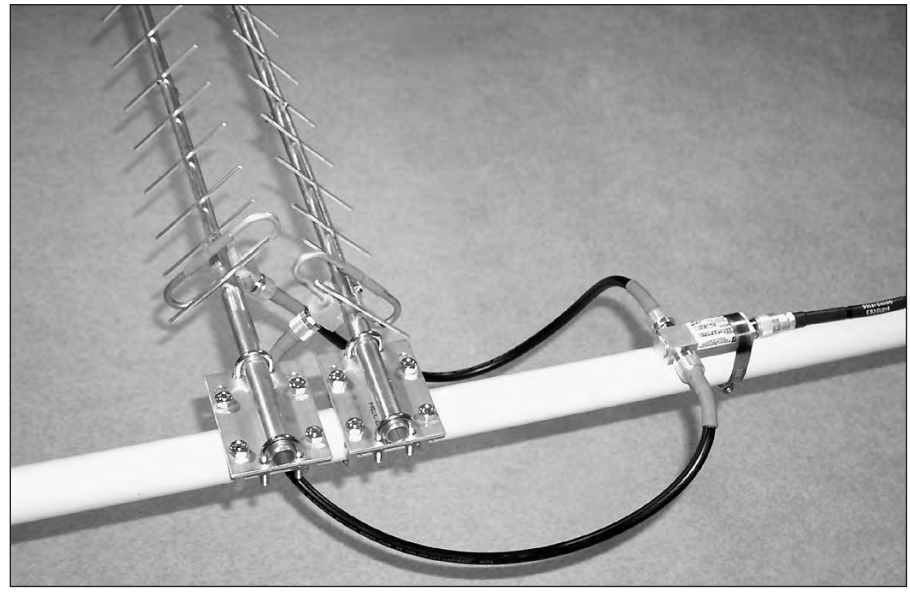

**Figure 17 — An example of offset crossed-Yagi circularly polarized antennas with fixed polarization. This example shows a pair of Yagis for L band (1296 MHz) mounted on an elevation boom. [KD1K photo]**

So far we've been discussing single-band crossed Yagi designs to achieve circular polarization, or something close to it. If circular polarization isn't a top criterion, you may want to consider a *dual-band Yagi* that places linear Yagi antennas for two separate bands on the same support boom. While this design doesn't produce circular polarization, it partially makes up for that disadvantage in convenience and economics. The most common design combines antennas for 2 meters and 70 centimeters on the same boom (**Figure 18**). You can feed the antennas with two separate feed lines, or use single feed line and a *diplexer* (some manufacturers incorrectly call them *duplexers*) to separate the signals at the antenna, at the radio or at both locations (**Figure 19**). With a single 2 meter/70 centimeter Yagi antenna you can enjoy nearly all available amateur satellites. That single-purchase aspect makes them attractive for budget-conscious hams.

A type of Yagi that you may encounter for higher frequencies (typically 902 MHz and above) is the *loop Yagi* (**Figure 20**). In this design, the individual elements are bent into loops and mounted on a common boom. Despite their appearance, loop Yagis are linearly polarized antennas. Their advantage is that they create a substantial amount of gain in a relatively small physical space. Because of the sizes of the loops, however, loop Yagis are most practical and common at microwave frequencies.

**Figure 18 — Joe Bottiglieri, AA1GW, uses a dual-band Yagi to work a low-Earth orbiting FM repeater satellite with a handheld transceiver.**

**Figure 19 — A diplexer made by the Comet Corporation. Diplexers can be used to separate or combine signals on different bands.**

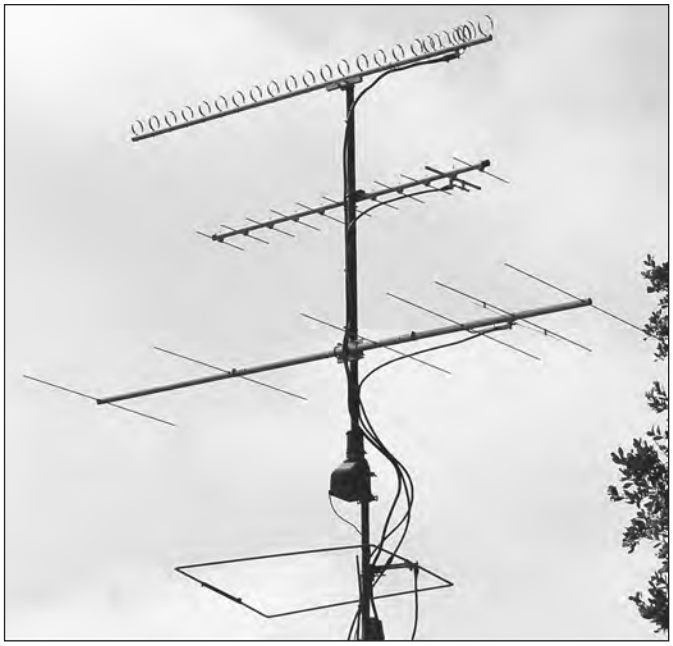

**Figure 20 — This antenna stack includes a loop Yagi at the very top.**

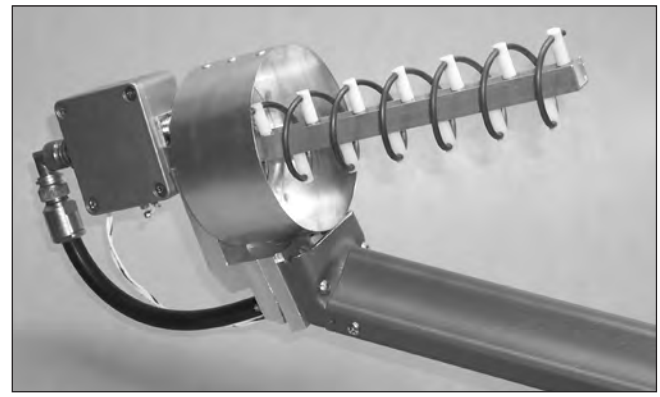

**Figure 21 — A seven-turn LHCP helical antenna for a 2.4 GHz dish feed. This helical antenna uses a cupped reflector and has a preamplifier mounted directly to the antenna feed point. [Dick Jansson, KD1K, photo]**

## HELICAL ANTENNAS

Another method to create a circularly polarized signal is by means of a helical antenna. The axial-mode helical antenna was introduced by Dr John Kraus, W8JK, in the 1940s. **Figure 21** shows an example of a microwave helical antenna. A larger helical for 70 centimeters is shown in **Figure 22**.

This antenna has two characteristics that make it especially interesting and useful for satellite stations. First, the helix is circularly polarized. As discussed earlier, circular polarization is simply linear polarization that continually rotates as it travels through space. In the case of a helical antenna, this rotation is about the axis of the antenna. This can be pictured as the second hand of a watch moving at the same rate as the applied frequency, where the position of the second hand can be thought of as the instantaneous polarization of the signal. The second interesting property of the helical antenna is its predictable pattern, gain and impedance characteristics over a wide frequency range. This is one of the few antenna designs that have both broad bandwidth and high gain. The benefit of this property is that, when used for narrow-band applications, the helical antenna is very forgiving of mechanical inaccuracies.

Electrically, a helix looks like a large air-wound coil with one of its ends fed against a ground plane. The ground plane often consists of a screen of 0.8 to 1.1 λ diameter (or per side for a square ground plane). The circumference of the coil form must be between

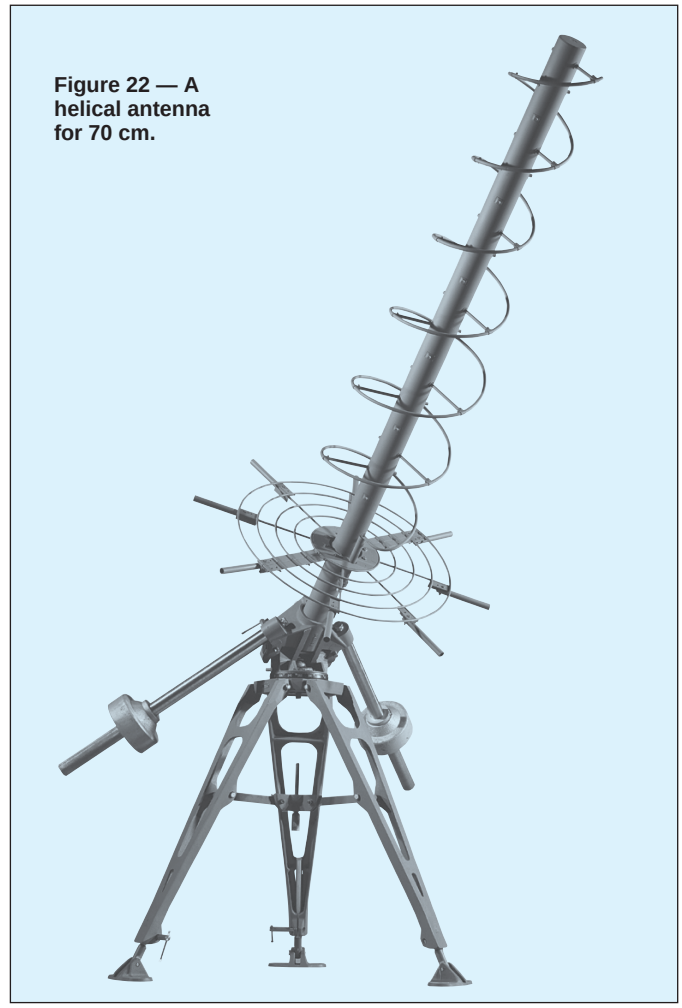

**Figure 22 — A helical antenna for 70 cm.**

0.75 and 1.33 λ for the antenna to radiate in the axial mode. The coil should have at least three turns to radiate in this mode. The ratio of the spacing between turns should be in the range of 0.2126 to 0.2867 λ. The winding of the helix comes away from the cupped reflector with a counterclockwise winding direction for LHCP. A clockwise winding direction yields RHCP.

## PARABOLIC DISH ANTENNAS

A number of modern ham satellites now include microwave transponders and this has created a great deal of interest in effective microwave antennas. From the ground station "point of view," antennas for the microwave bands are not only small, they pack a high amount of gain into their compact packages. Among the best high-performance antenna designs for microwave use are those that employ parabolic reflectors (so-called parabolic "dishes") to concentrate the transmitted and received energy.

Like a bulb in a flashlight, a parabolic antenna must have a *feed source* — the radiating and receiving part of the antenna — "looking" into the surface of the dish. Some dishes are designed so that the feed source is mounted directly in front of the dish. This is referred to as a *center-fed dish* (**Figure 23**). Other dishes are designed so that the feed source is off to one side, referred to as an *off-center-fed dish*, or just offset fed dish, as shown in **Figure 24**. The offset-fed dish may be considered a side section of a center-fed dish. The center-fed dish experiences some signal degradation due to blockage by the feed system, but this is usually an insignificantly small amount. The offset-fed dish is initially more difficult to aim, since the direction of reception is not the center axis, as it is for center-fed dishes.

The dish's parabola can be designed so the *focus point* — the point where the feed source must be — is closer to the surface of the dish, referred to a *short-focal-length* dish, or further away from the dish's surface, referred to as a *long-focal-length* dish. To determine the exact focal length (F), measure the diameter of the dish (D) and the depth of the dish (d).

$F=D^2 / 16d$

The focal length divided by the diameter of the dish gives the *focal ratio*, commonly shown as f/D. Center-fed dishes usually have short-focal ratios in the range of f/D = 0.3 to 0.45. Offset-fed dishes usually have longer focal lengths, with f/D = 0.45 to 0.80. If you attach two small mirrors to the outer front surface of a dish and then point the dish at the sun, you can easily find the focus point of the dish. This is where you want to place the feed source.

To invoke the flashlight analogy again, the feed source should evenly illuminate the entire dish, and none of the feed energy should fall outside the dish's reflecting surface. However, *no* feed system is perfect in illuminating a dish. These so-called "spillover losses" affect the gain by either under-illuminating or over-illuminating the dish. Typical dish efficiency is 50%. That's 3 dB of lost gain.

A great feed system for one dish can be a real lemon on another. For example, if you can get your hands on a surplus offset-fed satellite TV dish, you may find a helical radiator is the best feed source. Designs range anywhere from 2 to 6 turns. The two-turn helices are used for very short focal-length dishes in the f/D = 0.3 region, and the 6-turn helices are used with typically longer-focal-length (f/D ~ 0.6), offset-fed dishes. Generally speaking, helix feeds work poorly on the short-focal length dishes, but really perform well on the longer-focal length, offset-fed dishes.

Parabolic antennas can be made from commercial or military surplus, including satellite TV dishes that you can "repurpose" in the finest amateur radio tradition. You will also find ham dealers selling so-called *barbecue* dishes that were originally designed for the Multichannel Multipoint Distribution Service, or "wireless cable TV" (see **Figure 25**). MMDS antennas come with built-in feed sources at

**Figure 24 — This is a good example of an offset-fed dish. Note the feed source at the bottom edge of the photo, pointing into the center of the parabola. Also note that this is a DirectTV satellite TV antenna that has been "repurposed" for Amateur Radio satellites!**

**Figure 25 — The 2.4 GHz satellite downlink antenna at ARRL Headquarters station W1AW is a so-called "barbeque grill" dish antenna originally designed for the Multichannel Multipoint Distribution Service (MMDS). These inexpensive antennas can be assembled and installed in minutes.**

**Figure 23 — As you can see, the feed source is directly in front, making this a center-fed dish.**

**Figure 26 — A basic antenna rotator; the light-duty variety used to turn TV antennas. The wire exiting the bottom of the rotator housing is the multiconductor cable responsible for power and control.**

**Figure 27 — The Yaesu G5500 azimuth/elevation rotator (left) and its control unit (right).**

the focal points, so all you have to do is connect the feed line and go. These are among the most popular dish antennas for amateur satellite enthusiasts.

## 4.4 Antenna Mounting

One beneficial characteristic of satellite antennas is that they can be installed close to the ground as long as the antenna can "see" as much of the unobstructed sky as possible. Signals to and from the satellite will already be traversing hundreds or thousands of free space. So, adding a few more feet of elevation to your ground station antenna won't perceptibly improve the strength of those signals. What such an arrangement *will* do, however, is needlessly increase the length of coax (and corresponding line losses) between your transceiver and your antenna.

If your antennas already have an unobstructed view of the sky from the ground, you usually won't need a tower or roof installation unless trees or buildings surround the antennas and block their upward view. Or, to put it another way, your antenna support only needs to be high enough to make sure the back end of the antenna array is far enough off the ground to prevent people from walking into it while it's pointing straight up.

What's more, and as we have already discussed, satellite antennas (particularly those of the circularly polarized variety) along with their associated rotators (discussed below) tend to create a more complex antenna arrangement than that used for ordinary HF or VHF/UHF terrestrial operation. So, mounting them close to the ground makes performing any needed adjustments or repairs a whole lot simpler.

## 4.5 Antenna Rotators

If you plan to use directional antennas and don't wish to manipulate them by hand, you will need to install an *antenna rotator* (**Figure 26**). Making the correct decision as to how much capacity the rotator must have is very important to ensure trouble-free operation.

Rotator manufacturers generally provide antenna surface area ratings to help you choose a suitable model. The maximum antenna area is linked to the rotator's torque capability. Some rotator manufacturers provide additional information to help you select the right size of rotator for the antennas you plan to use. Hy-Gain provides an *Effective Moment* value. Yaesu calls theirs a *K-Factor*. Both of these ratings are torque values in foot-pounds. You can compute the Effective Moment of your antenna by multiplying the antenna turning radius by its weight. So long as the effective moment rating of the rotator is greater than or equal to the antenna value, the rotator can be expected to provide a useful service life.

There are several rotator grades available to amateurs. The lightest-duty rotator is the type typically used to turn TV antennas. These rotators will handle smaller satellite antennas such as crossed Yagis. The problem with TV rotators is that they lack braking or holding capability. High winds can turn the rotator motor via the gear train in a reverse fashion, requiring realignment. Broken gears sometimes result.

The next grade up from the TV class of rotator usually includes a braking arrangement, whereby the antenna is held in place when power is not applied to the rotator. Generally speaking, the brake prevents antenna misalignment or gear damage on windy days. If adequate precautions are taken, this type of rotator is capable of holding and turning a stack of satellite antennas, including a parabolic dish which, by its nature, presents considerable wind loading. Keep in mind that as rotators increase in power, they become more expensive.

### AZIMUTH/ELEVATION ROTATOR

Perhaps the ultimate in operating convenience is the *azimuth/elevation (az/el) rotator*. This rotator is capable of moving your antennas horizontally (azimuth) and vertically (elevation) at the same time. There are well-designed models available from Yaesu (**Figure 27**) and Alfa Radio (**Figure 28**). You can operate these rotators manually, or con-

**Figure 28 — An az/el rotator made by Alfa Radio.**

nect them to your computer for automated tracking. The downside is that az/el rotators tend to be expensive, typically on the order of $600 or more at this writing.

If your budget can stand the strain, az/el rotators are clearly worth the investment. On the other hand, if cost is an issue, consider using a standard rotator instead. While a traditional rotator can only move your antennas in the azimuth plane (horizontally), you can strike a compromise by installing the antennas at a permanent 45° tilt (**Figure 29**). This configuration will allow you to work the vast majority of satellites with reasonable success. You won't be able to follow the satellite when it is overhead or near the horizon, but you'll enjoy the lion's share of every pass.

Regardless of which type you choose, proper installation of the antenna rotator can provide many years of dependable service. Sloppy installation can cause problems such as a burned out motor, slippage, binding and even breakage of the rotator's internal gear and shaft castings or outer housing. Most rotators are capable of accepting mast sizes of different diameters, and suitable precautions must be taken to shim an undersized mast to ensure dead-center rotation.

If you decide to install your rotator on a tower, it is desirable to mount the rotator inside and below the top of the tower as far as possible. A long mast (10 feet or so) absorbs the torsion developed by the antenna during high winds, as well as during starting and stopping. Another benefit is mitigating the effect of any misalignment among the rotator, mast and the top of the tower.

A tube at the top of the tower (a *sleeve bearing*) through which the mast protrudes almost completely eliminates any lateral forces on the rotator casing. All the rotator must do is support the downward weight of the antenna system and turn the array. Some installations use a *thrust bearing* mounted to the tower to support the weight of the antenna and mast.

Don't forget to provide a loop of coax to allow your antenna to rotate properly and allow water to drip off. Also, make sure you position the rotator loop so that it doesn't snag on anything.

## COMPUTER CONTROL

As mentioned earlier, you can connect your rotator to your station computer and allow your satellite-tracking software to aim your antennas automatically (assuming your software supports rotator control). There used to be a number of commercial rotator/computer interface devices available for sale, but availability has dwindled over the years and those that remain tend to be expensive. An interface such as the Yaesu GS-232 (**Figure 30**) costs about $600 at the time of this writing. If you combine it with a Yaesu azimuth/elevation rotator, you will have invested $1300 total. Less expensive alternatives are now found as kits or homebrew devices. A good example is the G6LVB tracker interface at **www.g6lvb.com/Articles/LVBTracker/**. If you're willing to build it yourself, you can probably put together an LVB unit for less than $50. Do an internet search and you'll no doubt uncover other homebrew interfaces.

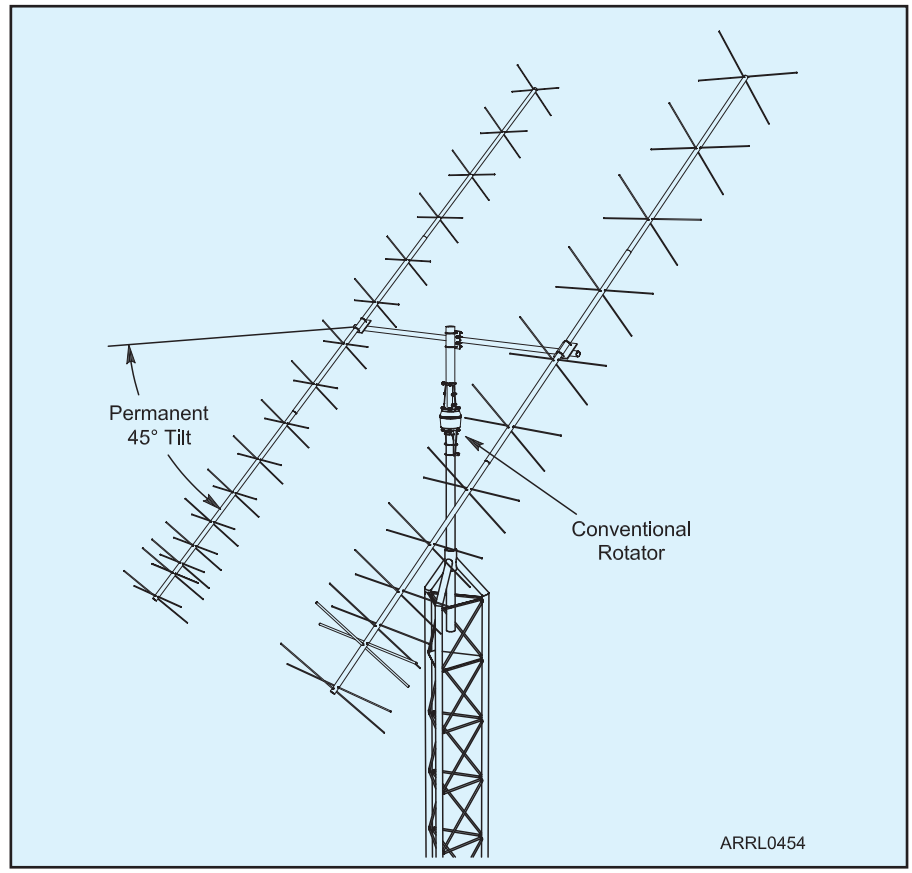

**Figure 29 — The alternative to using an expensive azimuth/elevation antenna rotator is to simply install your antennas at a 45° tilt and use a conventional rotator to move them from side to side (azimuth only). This configuration will allow access during most satellite passes.**

**Figure 30 — The Yaesu GS-232 allows your computer and satellite tracking software to automatically control the movements of compatible azimuth/elevation antenna rotators.**

# 5 Satellite Ground Station Equipment

## 5.1 Receive and Transmit Converters

Signals from satellites can be exquisitely weak, which means they need as much amplification as possible to be readable. Unfortunately, there are a number of factors that may conspire to weaken your radio's ability to render a decent received signal….

- *You're using omnidirectional antennas.* As discussed earlier, omni antennas lack much of the signal-capturing gain of directional antennas.
- *The feed line between the antennas and the radio is long and/or contains "lossy" coax.* Remember that even with the best coax, the longer the feed line the more signal you'll lose, especially at higher frequencies.
- *You're trying to communicate with a high-orbiting satellite at apogee.* When a signal travels up to 50,000 km to reach your station, even the gain of a directional antenna may not be sufficient.

### PREAMPLIFIERS

The way to ensure that you have a useable received signal is to install a *receive preamplifier* (**Figure 31**) at the antenna. This is a high-gain, low-noise amplifier with a frequency response tailored for one band only.

When shopping for a receive preamplifier, you want the most amount of gain for the least amount of noise. Every preamplifier adds some noise to the system, but you want the least additional noise possible. A well-designed UHF preamplifier, for example, may have gain on the order of 15 to 25 dB and a *noise figure* (NF) of 0.5 to 2 dB (less is better).

If your antennas are outdoors, look for preamplifiers that are "mast mountable." These preamplifiers are housed in weatherproof enclosures.

You will need to devise a means to supply dc power to the remote preamplifier. This can be as simple as routing a two-conductor power cable to the device. Alternatively, preamplifiers can be powered by dc sent up the feed line itself. Some transceivers have the ability to insert 12 V dc on the feed line for this purpose. If not, you can use a *dc power inserter* to inject power at the station and/or recover it nearer the antenna (see **Figure 32**). Some preamplifier designs include feed line power capability, so all you need is an inserter at the "station end."

If your preamplifier is going to be installed in a feed line that will also be carrying RF power from the radio, you'll need a model that includes an internal relay to temporarily switch it out of the circuit to avoid damage to the preamplifier when you're transmitting. Some preamplifiers include this relay and nothing more; it is up to you to provide the means to energize the relay before you transmit. This is accomplished through a device known as a *TR sequencer*. A sequencer works with your transceiver to automatically switch the preamplifier out of the feed line before the radio can begin sending RF power (see **Figure 33**). A less complicated alternative is

**Figure 31 — This receive preamplifier by Advanced Receiver Research gives signals a substantial boost before they travel down the coaxial cable to your radio.**

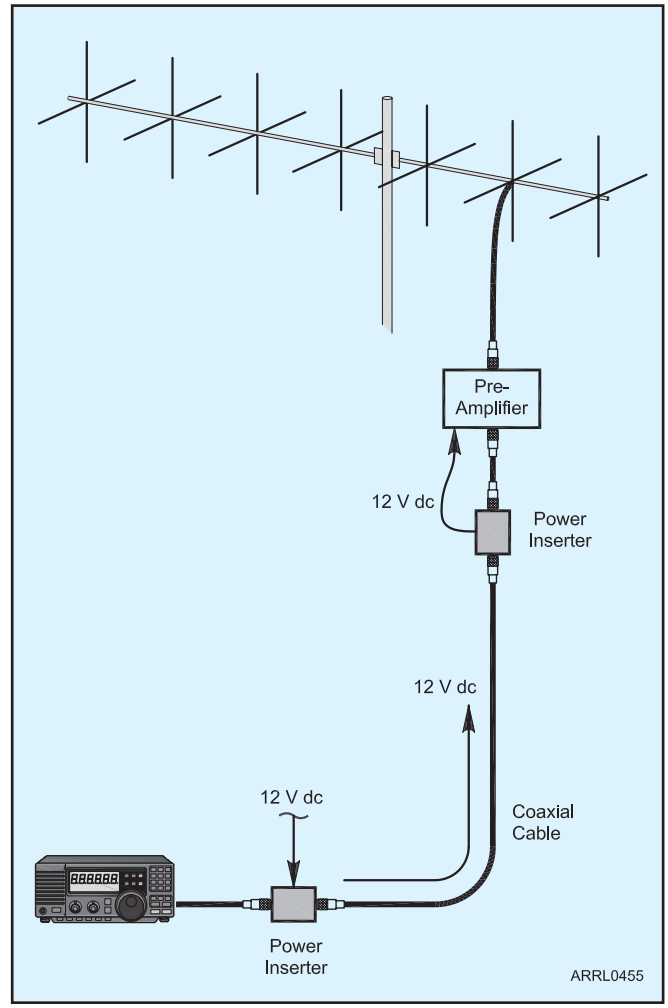

**Figure 32 — A dc power inserter acts just as its name implies — it inserts a dc voltage to the coaxial cable at the station. The inserter is designed to block dc power from going "backward" to the radio. Instead, the power flows through the coax to the antenna where another inserter picks it off and supplies it to the device (a preamplifier, in this case). Both inserters pass RF with negligible loss.**

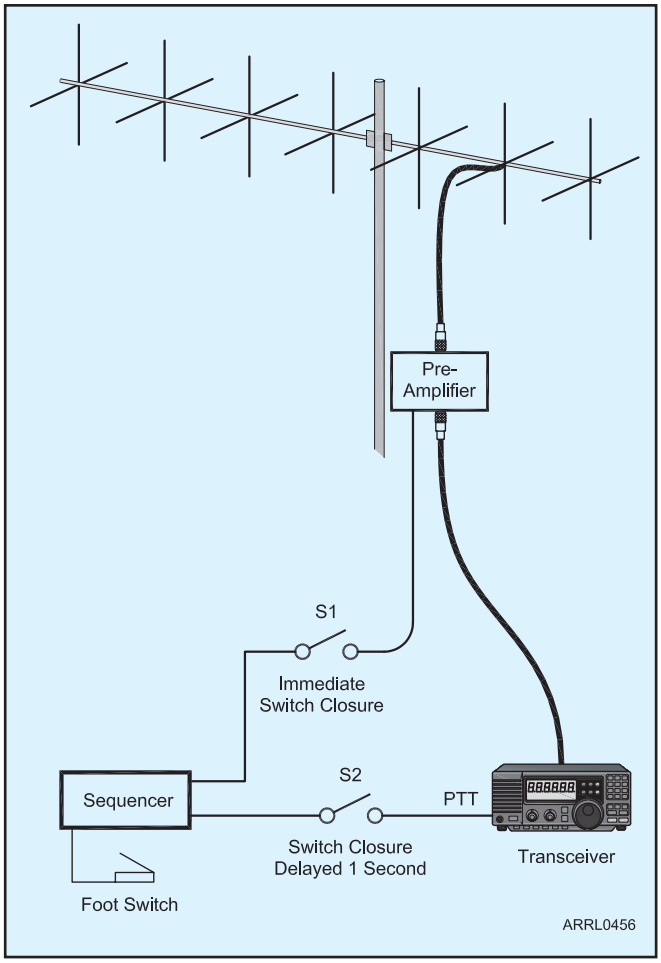

**Figure 33 — In this simplified example, the sequencer is triggered when the operator presses the foot switch. It immediately closes switch S1, which activates a "bypass" relay in the receive preamplifier at the antenna, effectively removing it from the feed line circuit. One second later, the sequencer closes switch S2, which is connected to the transceiver PTT (Push To Talk) line, keying the radio and applying RF power.**

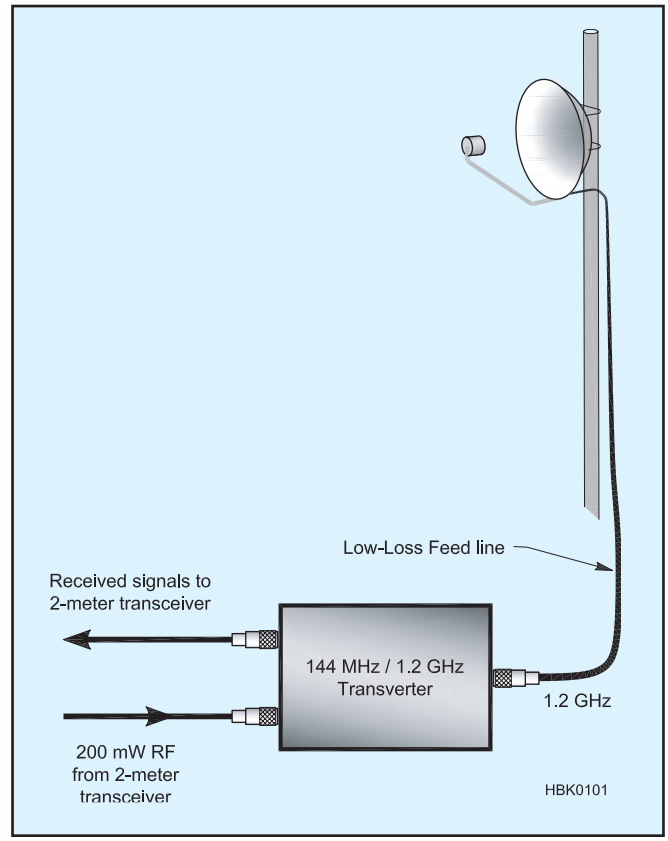

**Figure 34 — In this example, the transverter is taking 1.2 GHz received signals and converting them to 2 meters. When it's time to transmit, the transverter takes RF at 2 meters and converts it to 1.2 GHz.**

to purchase a preamplifier with *RF-sensed switching*. This design incorporates a sensor that detects the presence of RF from the radio and instantly switches the preamplifier out of harm's way. Note that RF-switched preamplifiers are rated according to the power they can safely handle. If you're transmitting 150 W, you'll need an RF-switched preamplifier rated for 150 W or more.

## TRANSVERTERS

Transverters convert received and transmitted signals from one band to another. You can use a transverter to generate, say, a 1.2 GHz uplink signal when powered by RF energy from a 2 meter transceiver. The same transverter can convert 1.2 GHz downlink signals to 2 meters as well (**Figure 34**).

Transmit/receive switching in most transverters is accomplished through the use of an internal switch that is keyed through a sequencer. Some models provide automatic RF-sensed switching.

When working with transverters, one issue is supplying a safe level of RF power to the input. If your transceiver pumps out 50 W of power at 2 meters, for example, this is way too much RF for most transverters to handle. Unless the transverter has a built-in RF power attenuator, it is designed to deal with RF power levels on the order of *milliwatts* (typically 200 to 300 mW). If you are lucky enough to own a transceiver that features a transmit transverter port, you can obtain your milliwatt power levels there. If not, you'll need to add an attenuator at the transverter input to reduce the RF output of your radio to safe levels.

## DOWNCONVERTERS

As the name implies, a *downconverter*, also known as a *receive converter*, converts one band of frequencies "down" to another. For example, a 2-to-10-meter downconverter would convert signals in a range from 144 to 146 MHz to 28 to 30 MHz.

In the days before HF/VHF/UHF transceivers, a downconverter was a popular means of receiving VHF and UHF signals by converting them to 10 meters (usually) for reception on an HF receiver. Today downconverters are used more often as a way to receive microwave signals, for example converting a range of frequencies at 2.4 GHz to 2 meters. A microwave downconverter works best when installed right at the antenna so that the microwave energy is immediately converted to a lower frequency before excessive feed line loss can occur. See **Figure 35**.

Like receive preamplifiers, downconverters are rated by their gain and NF (the lower the NF, the better). When it comes to installing a downconverter, all the same receive preamplifier issues apply. If the downconverter is installed outdoors it must be in a weatherproof enclosure. You must also supply dc power and be able to switch the downconverter out of the line if you are sending RF power to the same antenna.

**Figure 35 — This downconverter by Downeast Microwave converts signals at 2.4 GHz to 2 meters. With its weatherproof enclosure, it is designed to be installed at the antenna.**

**Figure 36 — The ICOM IC-2820 FM transceiver can receive and transmit on 2 meters and 70 centimeters independently. With a dual-band FM rig like this, you can communicate through the FM repeater satellites, even while mobile.**

**Figure 37 — The Kenwood TM-D710 is a dual-band FM transceiver with a built-in packet radio Terminal Node Controller (TNC) for digital communication.**

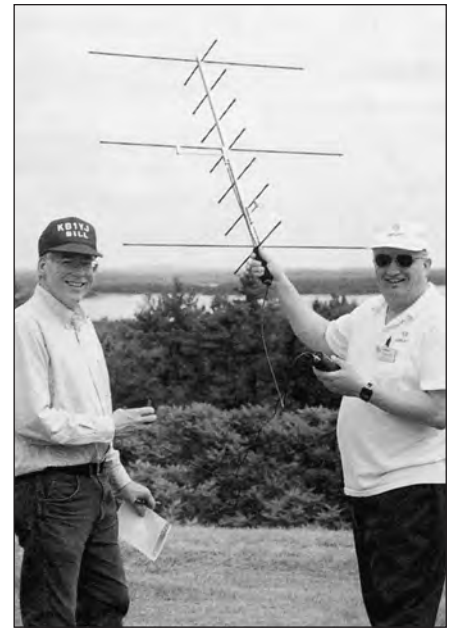

**Figure 38 — The hand-held Arrow gain antenna is popular for FM repeater satellite operations. This is a dual band version for 2 meters and 70 centimeters. [AMSAT photo]**

## 5.2 Transceivers

There are many amateur transceivers that cover the VHF and UHF bands. Some popular radios offer all the HF bands as well. Some of these transceivers offer satellite-specific features, while others are oriented toward terrestrial operation.

### WORKING WITH FM REPEATER AND DIGITAL SATELLITES

Almost any dual-band (2 meter/70 centimeter) FM transceiver will be adequate for operating FM repeater satellites such as OSCAR 27, and for digital operating with the International Space Station or LEO orbiting birds as well (**Figure 36**). Getting started with a dual-band FM radio and a repeater satellite is a worthwhile option.

Most modern dual-band rigs offer a "high power" output setting around 50 W. That's more than enough power to put a solid signal into a satellite with a directional antenna. It is also sufficient for omnidirectional antennas, including mobile antennas. (Yes, you can make contacts through FM repeater satellites while you drive!)

If you are considering digital operation, make sure to choose an FM transceiver that offers a data port. This will make it much easier to connect an external radio modem, such as a packet radio terminal node controller (TNC). There are even a few radios with TNCs already built in (**Figure 37**). Also, make sure the transceiver is rated to handle 1200 and 9600 baud data signals. Nearly all FM transceivers can work with 1200 baud, but not all can do 9600 baud.

You can use dual-band handheld transceivers to work the FM birds, but their RF output is so low (5 W or less) that you will definitely need to couple them to directional antennas to be heard consistently among the competing signals (**Figure 38**). What's more, at this writing, most of the newer handhelds will *not* allow so-called true (or "full") duplex operation. We will discuss what full-duplex means and why it is desirable for satellite work in a moment.

### WORKING WITH LINEAR TRANSPONDER (SSB/CW) SATELLITES

FM signals tend to be wide and, by design, FM receivers are forgiving of frequency changes. That fortunate characteristic makes it easy to compensate for Doppler frequency shifting as an FM repeater satellite zips overhead.

SSB and CW signals are much narrower, however, and when you're working through a linear transponder satellite your signal is sharing the passband with several others. Not only do you need to adjust your receive (downlink) frequency almost continuously to keep the SSB voice or CW sounding "normal," you also have to stay on frequency to avoid drifting into someone else's conversation. The most effective way to do this is to listen to your own signal coming through the satellite in real time while you are transmitting on the uplink. This type of operation is known as *full duplex*.

You will find many multimode (SSB, CW, FM) transceivers that boast a feature labeled "cross-band split" or even "cross-band duplex." Be careful, though. What you require is a radio that can transmit and receive on different bands *simultaneously*. Few amateur transceivers can manage such a trick!

As this book went to press, there was only one all-mode amateur transceiver on the market capable of full duplex operation: The VHF/UHF Icom IC-9700 (**Figure 39**). However, if you shop the used equipment market you'll find excellent satellite radios such as the and the all-band Kenwood TS-2000 (**Figure 40**), Yaesu FT-736 (**Figure 41**), the Icom IC-820 and IC-910H, the Yaesu

**Figure 39 — As of 2021, the Icom IC-9700 was the only all-mode transceiver available in the amateur radio market with full-duplex capability for satellite work.**

**Figure 40 — The Kenwood TS-2000 is no longer manufactured, but it is still common on the used market. The transceiver offers full HF coverage, plus VHF and UHF with full-duplex satellite capability.**

**Figure 41 — The Yaesu FT-736 is a legendary satellite transceiver. Although no longer manufactured, the '736 is still available on the used market.**

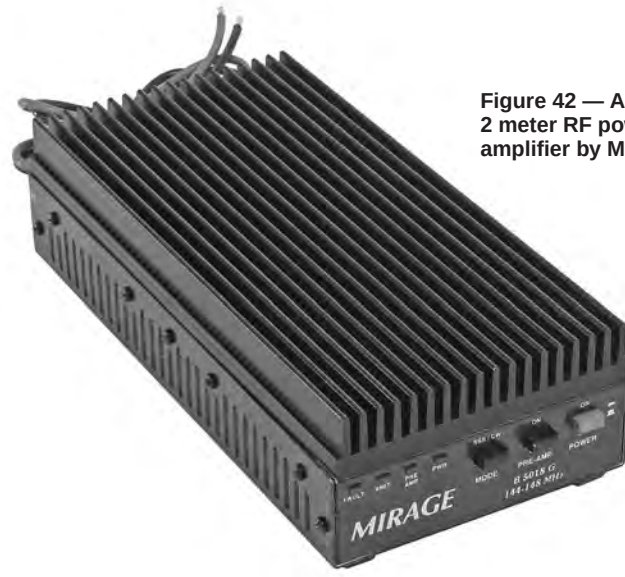

**Figure 42 — A 160 W 2 meter RF power amplifier by Mirage.**

FT-726 and FT-847 along with the Kenwood TS-790. All of these transceivers have full-duplex capability.

Another option that some hams have used successfully is to exploit computer control of their ordinary non-duplex multiband transceivers to compensate for Doppler shift. Some satellite-tracking programs can automatically change the frequency of your radio during a pass. They do this by mathematically calculating the frequency shift and tweaking your radio accordingly. This solution for frequency stability isn't as accurate as listening to your own downlink signal in full duplex, but it can work.

Another option is to use one transceiver for the uplink and a separate receiver or transceiver for the downlink. Some amateurs have even pressed old shortwave receivers into service along with VHF or UHF downconverters. They transmit with a 2 meter or 70 centimeter SSB radio on the uplink while listening to their shortwave receiver/downconverter combo on the downlink.

If you are working a linear transponder satellite with an uplink at 1.2 GHz or higher, you'll likely have to take the transverter approach to getting on the air, although there are some transceivers that offer optional 1.2 GHz modules. Fortunately, satellite builders are well aware that most hams own 2 meter and 70 centimeter transceivers and they design new birds accordingly. Even transponders with microwave downlinks are usually configured with uplinks on 2 meters or 70 centimeters. So, if you purchase a VHF/UHF transceiver all you need to add is a downconverter to receive the microwave downlink.

## 5.3 VHF/UHF RF Power Amplifiers

If your chosen transceiver offers at least 50 W output on the uplink band, you won't need an RF power amplifier to bring your signal to a level that can be "heard" by a LEO satellite, especially if you are using directional antennas.

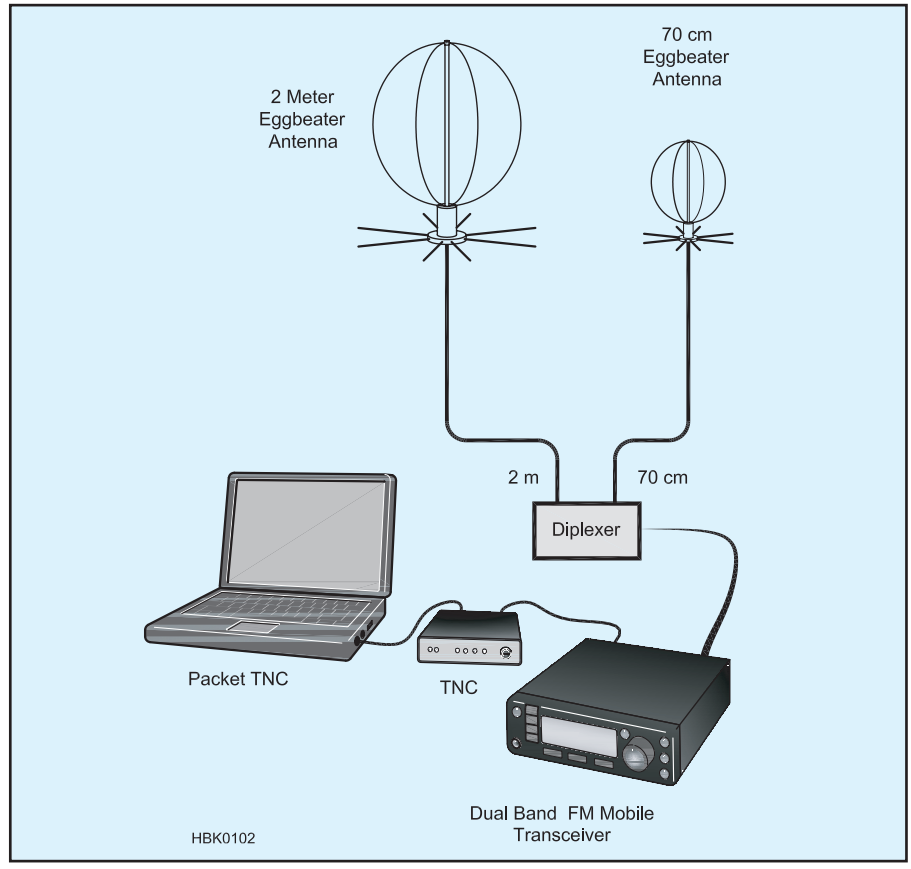

**Figure 43 — A basic FM voice and data station for LEO satellites. At its core is a dual-band FM transceiver rated for 30 to 50 W output at its "high power" setting. This example uses omnidirectional antennas and it presumes that the FM transceiver has only one antenna jack, which is why a diplexer is indicated.**

On the other hand, if you are using omni antennas, 100 or 150 W output may help considerably. And if your target is an HEO satellite orbiting at 50,000 km, 100 W or more, along with a directional antenna, is *mandatory*. If your transceiver lacks the necessary punch for the application, the solution is an external RF power amplifier.

How much power should you buy? In most cases, a 100 or 150 W amplifier is a good choice (**Figure 42**). As you shop for amplifiers, take care to note the input and output specifications. How much RF at the input is necessary to produce, say, 150 W at the output? Can your radio supply that much power?

Another consideration is your dc power supply. While a 25 A 13.8 V dc supply is perfectly adequate to run a 100 W transceiver, if you also decide to add a 100 or 150 W amplifier to your satellite station, the current demands will increase considerably. A separate power supply may be required to provide an *additional* 20 A (or more) to safely power the amplifier when both the transceiver *and* the amplifier are transmitting at the same time.

## 5.4 Typical Station Designs

There are so many station equipment options available, it may be helpful to outline a few typical station configurations.

**Figure 43** illustrates a basic FM voice and data station for LEO satellites. At its core is a dual-band FM transceiver rated for 30 to 50 W output. The example uses omnidirectional antennas and it presumes that the FM transceiver has only one antenna jack, which is why a diplexer is indicated. Otherwise, you could run two separate coaxial feed lines back to the radio.

The performance of this station can be substantially enhanced by adding directional antennas or a dual-band Yagi but, of course, that will require an antenna rotator (human or mechanical!).

In **Figure 44** we've stepped up to a multiband, multimode transceiver with full duplex capability and directional antennas. This station would be excellent for LEO satellites with linear SSB/CW transponders, as well as FM voice and data. By adding an RF power amplifier (assuming the output of the radio is less than 100 W), this station would be capable of working distant high-orbiting satellites as well.

Note that this illustration shows two separate antennas and feed lines. You could just as easily use a single dual-band Yagi antenna and one feed line. However, you may need a diplexer at the radio if it employs separate VHF and UHF antenna jacks.

**Figure 45** addresses at least one method to work satellites with microwave downlinks. It assumes that the uplink is at 70 centimeters and the downlink is at 2.4 GHz. It also assumes that the satellite in question is a high-orbiting spacecraft (note the RF power amp on the uplink).

Note also the use of the downconverter

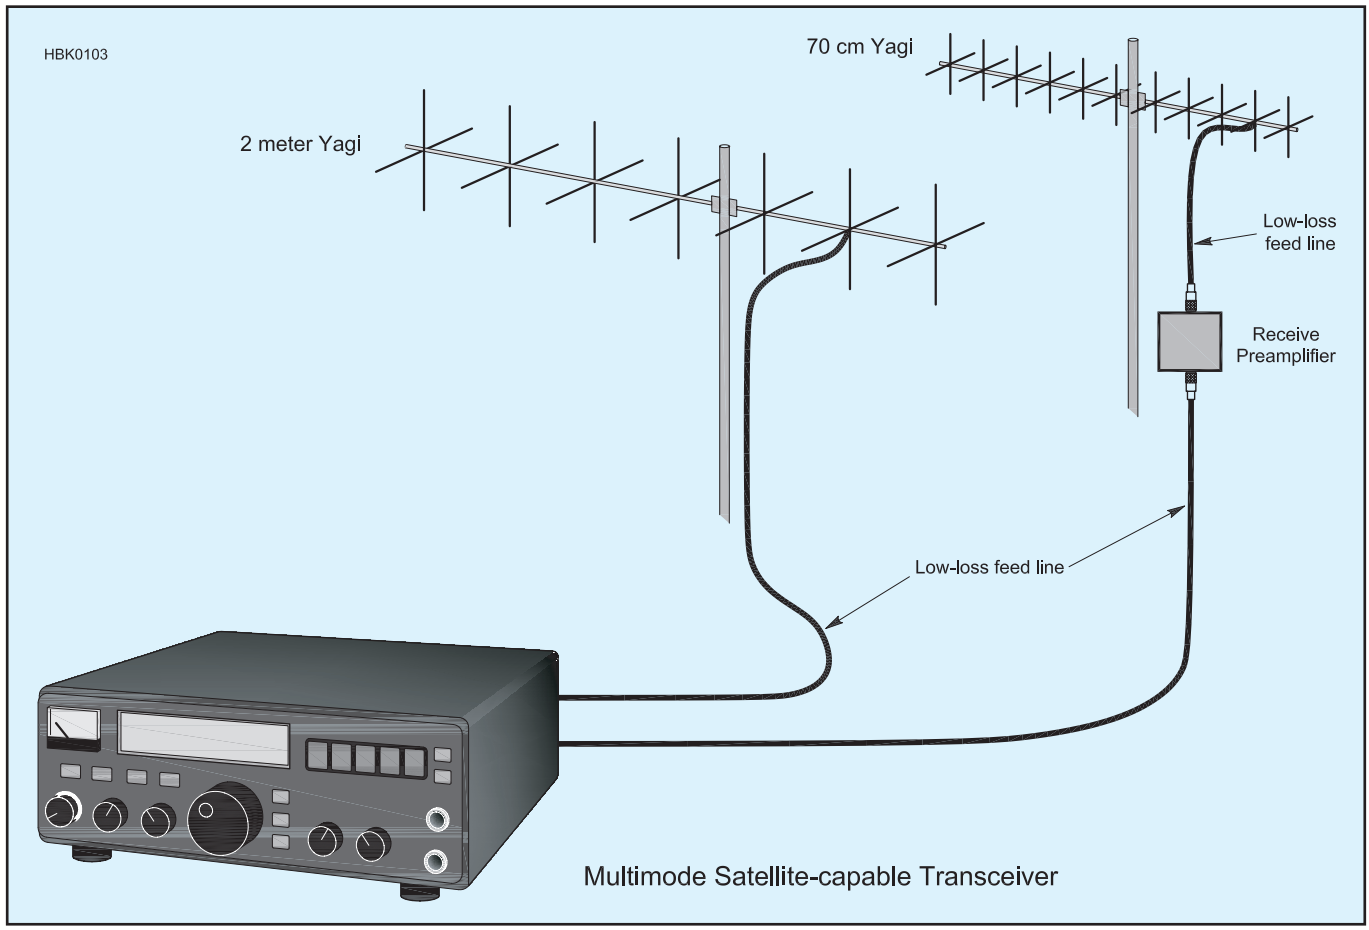

**Figure 44 — This station would be adequate for LEO satellites with linear SSB/CW transponders such as OSCAR 52, as well as FM voice and data. This illustration shows two separate antennas and feed lines. You could just as easily use a single dual-band Yagi antenna and one feed line. However, you may need a diplexer at the radio if it employs separate VHF and UHF antenna jacks.**

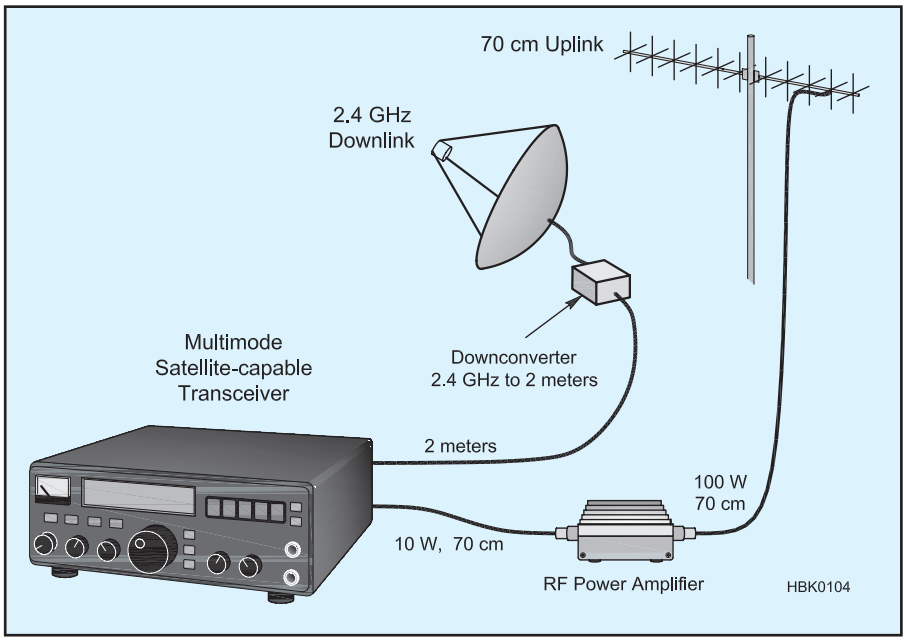

**Figure 45 — This example illustrates a station designed to work a distant Phase III or IV satellite with a microwave downlink. It assumes that the uplink is at 70 cm and the downlink is at 2.4 GHz. Note the use of the downconverter to step the 2.4 GHz signal at the antenna down to 2 meters before it is fed to the radio.**

to step the 2.4 GHz signal at the antenna to 2 meters before it is fed to the radio. You can actually use this same approach for any combination of bands and radios. For instance, let's say that you want to work the low-orbiting FM birds, but you have only a 2 meter FM transceiver for the uplink and a separate VHF FM police scanner receiver for the downlink. You could use a downconverter for the 70 centimeter downlink, stepping the signal down to 2 meters for reception with the scanner (**Figure 46**.

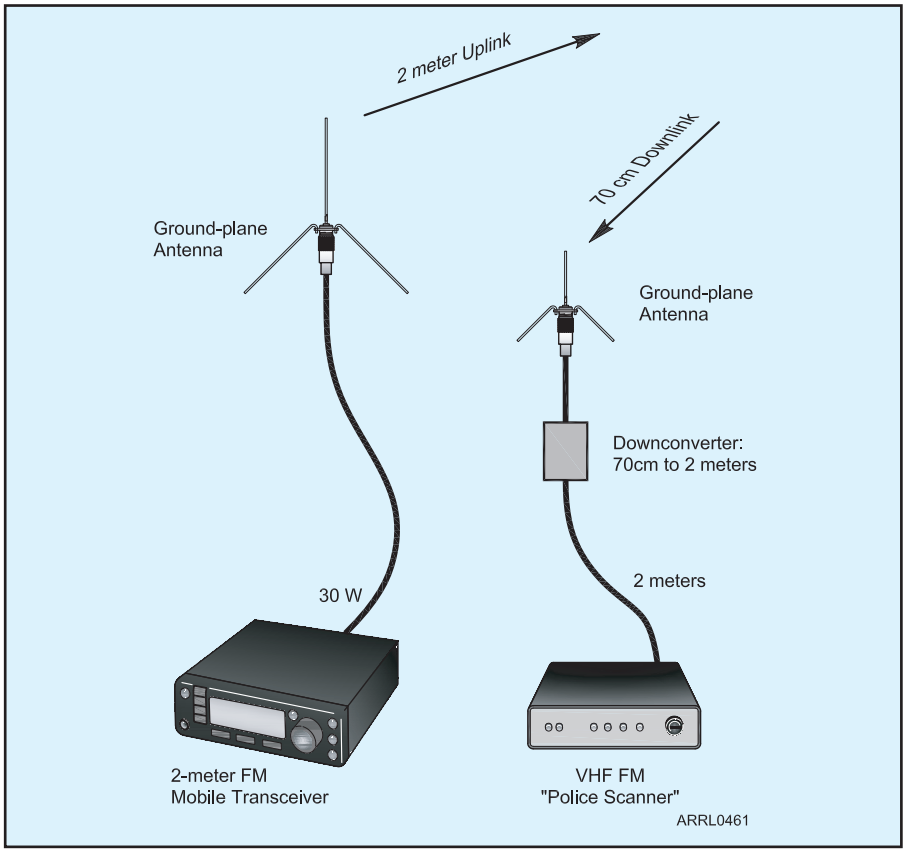

**Figure 46 — Let's say that you want to work the low-orbiting FM birds, but you only have a 2 meter FM transceiver for the uplink and only a VHF FM "police scanner" receiver for the 70 cm downlink. You could use a downconverter for the 70 cm downlink, stepping the signal down to 2 meters for reception with the scanner.**

# 6 Satellite Antenna Projects

## 6.1 An EZ-Lindenblad Antenna for 2 Meters

This easy-to-build antenna project by Anthony Monteiro, AA2TX, works well for satellite or terrestrial communication. It is circularly polarized yet has an omnidirectional radiation pattern (no rotator needed to track satellites). With most of its gain at low elevation angles, it is ideal for accessing LEO amateur satellites. It is good for portable operation or general-purpose use at home stations because its circular polarization is compatible with the linearly polarized antennas used for FM/repeater and SSB or CW operation.

This type of antenna was devised by Nils Lindenblad of the Radio Corporation of America (RCA) around 1940. His idea was to employ four dipoles spaced equally around a λ/3 diameter circle with each dipole canted 30° from the horizontal. The dipoles are all fed in phase and are fed equal power. The spacing and tilt angles of the dipoles create the desired antenna pattern when the signals are all combined. After WWII, George Brown and Oakley Woodward, also of RCA, were tasked with finding ways to reduce fading on ground-to-air radio links at airports and built on Lindenblad's design.

While the Brown and Woodward design is clever and worked well, it would be difficult for the home builder to duplicate because of the need for the four-way, in-phase, power splitting function. Since amateurs generally want to use 50 Ω coaxial cable feed line, we have to somehow provide an impedance match from the 50 Ω unbalanced coax to the four 75 Ω balanced dipole loads. Previous designs have used combinations of folded dipoles, open-wire lines, twin-lead feeds, balun transformers and special impedance matching cables to try to get a good match to 50 Ω. These in turn increase the complexity and difficulty of the construction.

### THE EZ-LINDENBLAD

The key concept of the EZ-Lindenblad is to eliminate anything electrically or mechanically difficult. This leads to the idea of just feeding the four dipoles with coax cable and soldering the cables to a connector with no impedance matching devices at all. This would certainly be *easy* but we also want the antenna to work! Without the extra impedance matching devices, how is it possible to get a good match to 50 Ω?

If we could get each of the four coax feed cables to look like 200 Ω at the connector, then the four in parallel would provide a perfect match to 50 Ω. We could do this if we used 1/4 λ sections of 122 Ω coax to convert each 75 Ω dipole load to 200 Ω. Unfortunately, there is no such coax that is readily available.

But we can accomplish the same thing with ordinary 75 Ω, RG-59 coax if we run the cable with an intentional impedance mismatch. By forcing the standing wave ratio (SWR) on the cable to be equal to 200/75, or about 2.7:1, we can make each cable look exactly like 200 Ω at the connector as long as we make them the right length. It is easy to make the SWR equal 2.7:1 by just making the dipoles a little too short for resonance. An *EZNEC* (**www.eznec.com**) antenna model can be used to determine the exact dipole dimensions.

The conversion from the balanced dipole load to unbalanced coax cable can be accomplished by threading each cable through a ferrite sleeve making a choke balun. The only remaining issue is the required length of the feed cables. With a Smith Chart or software, we can easily determine the required length of 75 Ω coax to provide a 200 Ω load. An *EZNEC* antenna model was used to simulate cutting the dipole lengths until the SWR on the line reached 2.7:1. The model showed that the dipole load impedance would then be 49 –*j*55 Ω. Plotting that value and the desired 200 Ω impedance at the connector on the chart and drawing a constant 2.7:1 SWR curve between the two impedance points, the length of the line needed is 0.374 λ. (For more information about this process, see **www.arrl.org/smith-chart**.)

The EZ-Lindenblad was designed for a center frequency of 145.9 MHz to optimize its performance in the satellite sub band. At 145.9 MHz, a wavelength is about 81 inches and since the coax used has a velocity factor of 0.78, we need to make the feed cables 81 × 0.374 × 0.78 = 23.6 inches long.

It's imperative that stranded RG-59A foam PE dielectric coax be used. The solid-dielectric cable has a velocity factor of 66% and will not work. The author used part # RG59A-100 from **www.l-com.com**. This is a 100 ft roll; for one antenna you could buy L-Com part # CCF59-12, a 12 ft jumper, and cut it to the required length. Belden 9259 is another suitable cable.

### CONSTRUCTION

This antenna was designed to be rugged and reliable yet easy to build using only hand tools with all of the parts readily available as well (see **Table 5)**. Although not critical, the construction will be easier if the specified 17 gauge aluminum tubing is used since the inner wall of the tubes will be just slightly smaller than the outer wall of the PVC insert Ts used to connect them. If heavier gauge tubing is used, it will be necessary to file down the PVC insert Ts to make them fit inside the aluminum tubes.

Start by making a mounting bracket to mount the N-connector and the cross booms. Cut a ⅝ inch hole in one side of the short piece of angle stock and rivet or screw it to the bottom of the long piece of angle stock. The completed bracket with the connector and cables attached can be seen in **Figure 47**.

Next, cut the aluminum tubing to make the cross booms and dipole rods as shown in **Figure 48**. Drill holes for the sheet metal screws at each end of the cross booms but do not insert the screws yet. Attach the cross

**Table 5**

**Required Materials**

*Quantity one, unless noted.*

- Aluminum tubing, 17 gauge, 6 ft length of ¾ in OD, quantity 3. Available from Texas Towers, **www.texastowers.com**.
- Aluminum angle stock, 8 in length of 2 × 2 × 1/16 in
- Aluminum angle stock, 2 in length of 2 × 2 × 1/16 in for mounting connector.
- Screws, #8 × ½ in aluminum sheet metal, quantity 12.
- Screws, #8 × ½ in aluminum sheet metal or 3/16 in aluminum rivets, quantity 12.
- PVC insert T-connector, ½ × ½ × ½ in grey for irrigation polyethylene tubing. LASCO Fittings, Inc. Part# 1401-005 or equivalent. Available from most plumbing supply and major hardware stores, quantity 4.
- Plastic end caps (optional), black ¾ in, quantity 8.
- N-connector for RG-8 cable, single-hole, chassis-mount, female.
- Cable ferrite, Fair-Rite part #2643540002, quantity 4 (Mouser Electronics #623-2643540002).
- RG-59A polyethylene foam coax with stranded center conductor (Belden 9259 or equiv; *must* be foam PE dielectric with 78% velocity factor, not solid dielectric), 10 ft length.
- Copper braid, 4 in long piece.
- Ring terminal, uninsulated 22-18 gauge for 8-10 stud, quantity 4.
- Ring terminal, uninsulated 12-10 gauge for 8-10 stud, quantity 4.
- Heat shrink tubing for ¼ in cable, wire ties, electrical tape, as needed.
- Ox-Gard OX-100 grease for aluminum electrical connections.

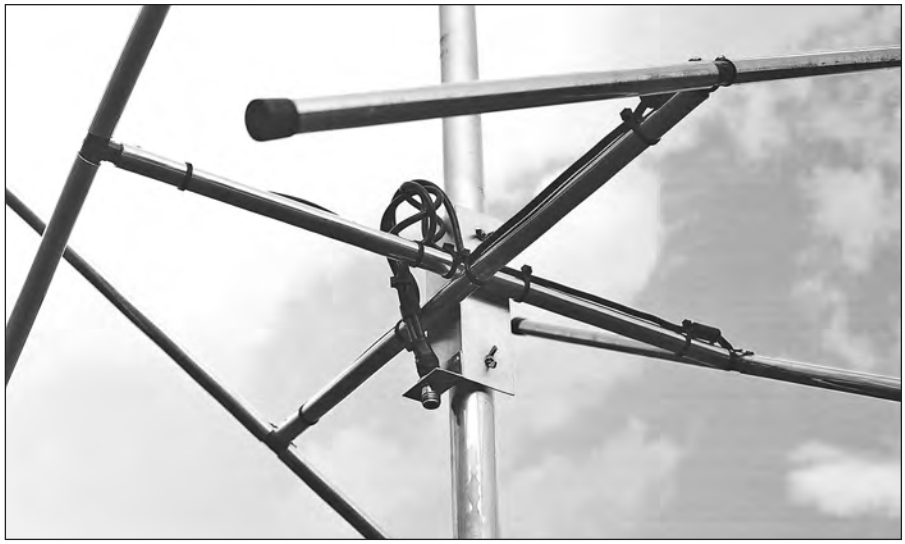

**Figure 47 — View of cross booms mounted to mast.**

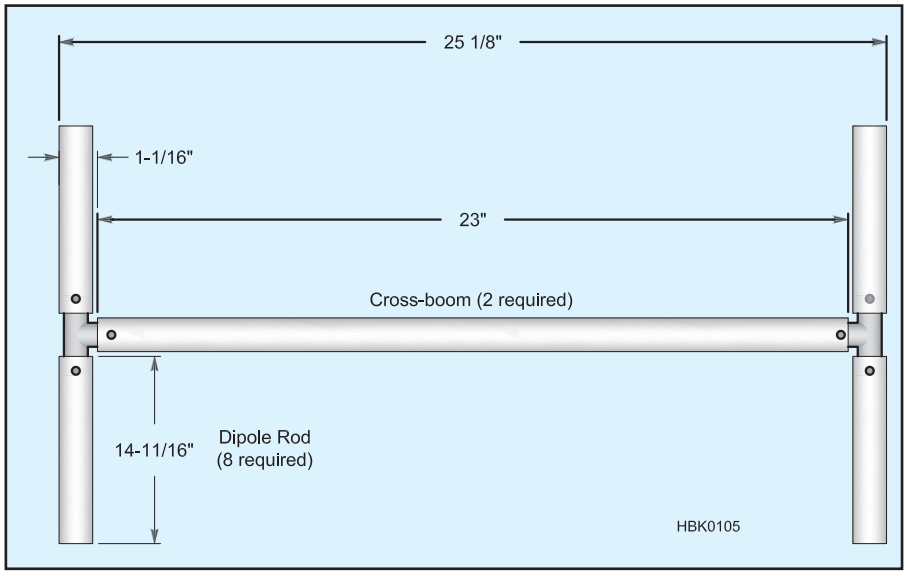

**Figure 48 — Dimensions of the dipoles and cross booms. The antenna requires two cross booms, with a dipole at each end of each cross boom (four dipoles total).**

booms to the long section of angle stock with rivets or screws. One cross boom will mount just above the other as can be seen in Figure 47. The cross booms should be perpendicular to the mounting bracket so that they will be horizontal when the antenna is mounted to its mast. Make sure that the centers of the cross booms are aligned with each other so that the ends of the cross booms are all 11.5 inches from the center cross.

Make the dipoles by inserting a PVC insert T into two dipole rods. It should be possible to gently tap in the rods with a hammer but it may be necessary to file down the insert T a little if the fit is too tight. Applying a little PVC cement to the insert T will soften the plastic and make it easier to insert into the aluminum tubing if the fit is too tight. The overall dipole length dimension is critical so take care to get this correct as shown in **Figure 49**.

Drill holes for screws in each dipole rod but do not insert the screws yet. The screws will be used to make the electrical connections to the dipoles at the center. The screw holes should be about ⅜ inches from the end of the tubing.

The dipole assemblies are attached by gently tapping the PVC insert-T into the end of each cross-boom with a hammer. The dimensions are shown in Figure 48.

Next, temporarily attach the mounting bracket to a support so that each of the cross booms is perfectly horizontal. Measure this with a protractor. Now, using the protractor, rotate the dipole assemblies to a 30° angle with the right-hand side of the nearest dipole tilting up when you are looking toward the center of the antenna. Drill a small hole through the existing cross-boom holes into the PVC insert-Ts and then use the sheet metal screws to fasten the dipole assemblies into place. For a nice finishing touch, the dipole ends can be fitted with ¾ inch black plastic end caps.

Next, make the four feed cables by cutting and stripping the RG-59A as shown in **Figure 50**. On the dipole connection side, unwrap the braid and form a wire lead. Apply the

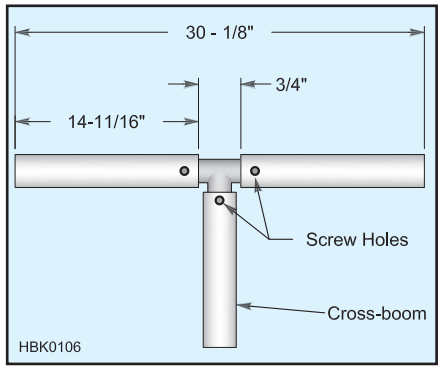

**Figure 49 — Dipole assembly dimensions.**

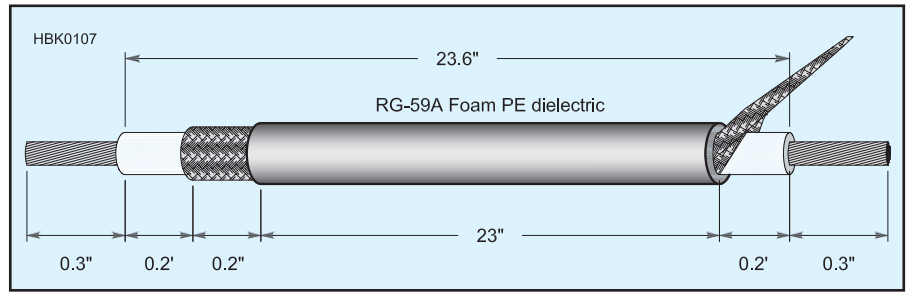

**Figure 50 — Feed cables stripping dimensions.**

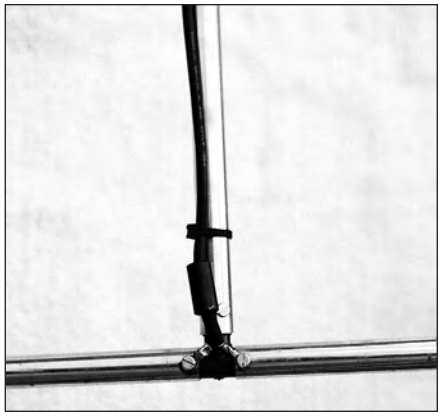

**Figure 51 — Close-up of dipole electrical connections.**

**Figure 52 — The EZ-Lindenblad as a portable or Field Day antenna. A 70 cm antenna is on the top.**

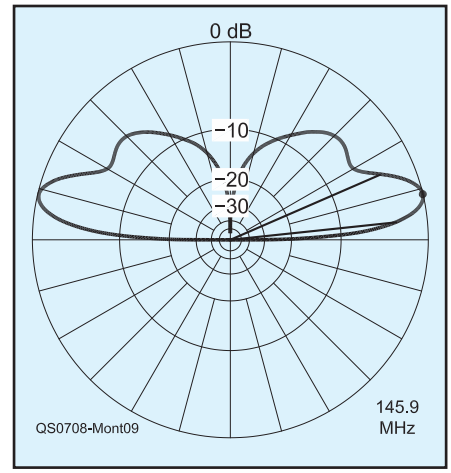

**Figure 53 — *EZNEC* elevation radiation pattern of Lindenblad antenna.**

smaller ring terminal to the center conductor and use the larger ring terminal for the braid. At the other end of the cable, do not unwrap the braid but strip off the outer insulation. Slip a 1 inch piece of shrink wrap over the coax and apply to the dipole side. Next slip a cable ferrite over the cable and push all the way to the dipole end as far as it will go (ie, up to the heat-shrink tubing.) The fit will be snug and you may need to put a little grease on the cable jacket to get it started.

Prepare each dipole for its feed cable by first cleaning the area around the screw holes with steel wool and then applying Oxy-Gard or other corrosion resistant electrical grease. The coax center conductor goes to the up side of the dipole and the braid goes to the down side. To make a connection, put a screw through the ring terminal and gently screw into the dipole tubing. Do not overtighten the screws or you will strip the tubing. **Figure 51** shows the completed connections.

Apply Oxy-Gard around the hole for the N connector. Take the 4 inch piece of braid and put the end of it through the hole for the N connector. This provides the ground connection. Secure the N connector in the mounting hole to clamp the braid. Use a wire tie or tape to hold the four feed cables together at the connector ends. Make sure to align the cables so that all the ground braids are together and the center conductors all extend out the same amount. Do not twist the center conductors together. Carefully push the four cable center conductors into the center terminal of the N connector and solder them in place. Wrap the exposed center conductors of the cables and the connector with electrical tape.

Take the piece of braid that is clamped to the N connector and wrap it around the four exposed ground braids of the coax cables. Solder them all together. This will take a fair amount of heat but be careful not to melt the insulation. After this cools, apply electrical tape over all the exposed braid and fix with wire ties. Secure the cables to the cross booms with wire ties.

The mounting bracket provides a way to attach the antenna to a mast using whatever clamping mechanism is convenient (eg, U-bolts). The author's antenna was intended for portable operation and the bracket was drilled to accept two #8 machine screws. These screws pass through a portable mast and the antenna is secured with wing nuts for easy setup. The completed portable antenna is shown in **Figure 52**. The little antenna at the top is for 70 centimeters.

### PERFORMANCE

The antenna impedance match to 50 Ω was tested using an MFJ-259B SWR meter, which was checked against an external frequency counter and precision 50 Ω load. The antenna provides an excellent match over the entire 2 meter band. This antenna was designed to safely handle any of the currently available VHF transceivers and tested by applying a 200 W signal key down for 9 minutes, then checking the ferrites and cables for temperature rise.

The antenna radiation pattern predicted by the *EZNEC* model is shown in **Figure 53**. This is the elevation plot with the antenna mounted at 6 ft above ground although it can be mounted higher if desired for better coverage to the horizon. As shown in the plot, the pattern favors the lower elevation angles. The –3 dB points are at 5° and 25° with the maximum gain of 4.8 dBic (dB with respect to an isotropic circularly polarized antenna) at around 13°. Most of the satellite pass elevations will be in this range and it is also the elevation at which the satellite provides the best chance for DX contacts. The antenna radiation is right-hand circularly polarized, which will work with virtually any LEO satellite that uses the 2 meter band.

The EZ-Lindenblad antenna has been used for SSB, FM and packet operation on a number of amateur satellites. A portable setup performed well on Field Day, an excellent test of any antenna as it is probably the busiest weekend of the year on the satellites.

## 6.2 The W3KH Quadrifilar Helix

If your existing VHF omnidirectional antenna coverage is "just okay," this twisted antenna project by Eugene F. Ruperto, W3KH, is probably just what you need! The ever-changing position of LEO satellites presents a problem for the Earth station equipped with a fixed receiving antenna: signal fading caused by the orientation of the propagated wavefront. This antenna provides a solution to the problem and can be used with weather satellites, or any of the polar-orbiting amateur satellites.

Several magazines have published articles on the construction of the quadrifilar helix antenna (QHA) originally developed by Dr Kilgus.[1] A particularly good reference is

[1]C. C. Kilgus, "Resonant Quadrafilar Helix;" *IEEE Transactions on Antennas and Propagation*, Vol AP-17, May 1969, pp 349-351.

*Reflections* by Walt Maxwell, W2DU, who had considerable experience evaluating and testing this antenna while employed as an engineer for RCA.[2]

Part of the problem of replicating the antenna lies in its geometry. The QHA is difficult to describe and photograph. Some of the artist's renditions leave more questions than answers, and some connections between elements as shown conflicted with previously published data. However, those who have successfully constructed the antenna say it is *the* single-antenna answer to satellite reception for the low-Earth-orbiting satellites.

## DESIGN CONSIDERATIONS

Experts imply that sophisticated equipment is necessary to adjust and test the antenna, but the author found it possible to construct successful QHAs by following a cookbook approach using scaled figures from a proven design. The data used as the design basis for the antenna described here were published in an article describing the design of a pair of circularly polarized S-band communication-satellite antennas for the Air Force and designed to be spacecraft mounted.[3] Using this antenna as a model, the author constructed QHAs for the weather-satellite frequencies and the polar-orbiting 2 meter and 70 centimeter amateur satellites with excellent results and without the need for adjustments and tuning. By following some prescribed universal calculations, a reproducible and satisfactory antenna can be built using simple tools.

UHF and microwave antennas require a high degree of constructional precision because of the antenna's small size. For instance, the antenna used for the Air Force at 2.2 GHz has a diameter of 0.92 inch and a length of 1.39 inches! On the other hand, a QHA for 137.5 MHz is 22.4 inches long and almost 15 inches in diameter; for 2 meters, the antenna is not much smaller. Antennas of this size are not difficult to duplicate.

## ELECTRICAL CHARACTERISTICS

A half-turn ½ λ QHA has a theoretical gain of 5 dBi and a 3-dB beamwidth of about 115°, with a characteristic impedance of 40 Ω. The antenna consists basically of a four-element, half-turn helical antenna, with each pair of elements described as a *bifilar,* both of which are fed in phase quadrature. Several feed methods can be employed, all of which appear complicated except the infinite-balun design, which uses a length of coax as one of the four elements.

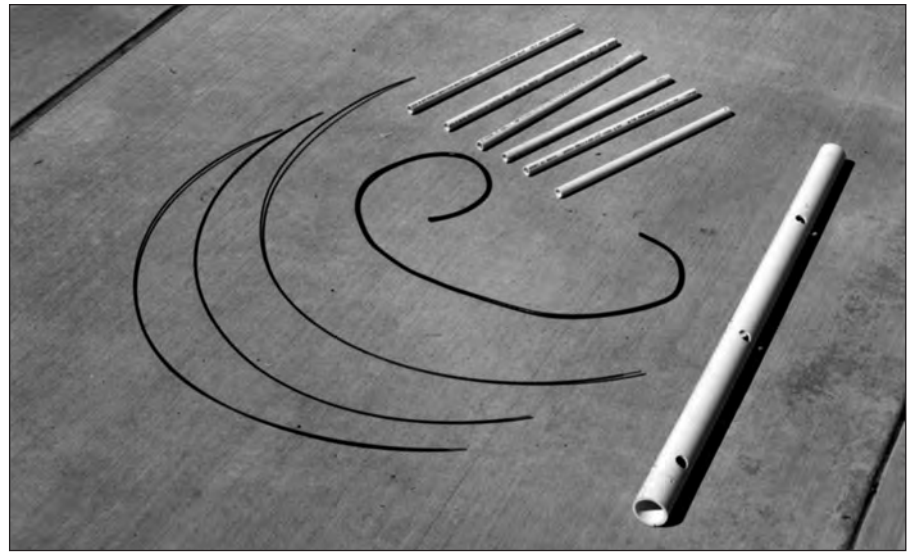

**Figure 54 — The quadrifilar helix antenna (QHA) pieces, ready for assembly.**

To produce the necessary 90° phase difference between the bifilar elements, either of two methods can be used. One is to use the same size bifilars, which essentially consist of two twisted loops with their vertical axes centered and aligned, and the loops rotated so that they're 90° to each other (like an egg-beater), and using a quadrature hybrid feed. Such an antenna requires *two* feed lines, one for each of the filar pairs.

The second and more practical method is the self-phasing system, which uses *different-size loops:* a larger loop designed to resonate *below* the design frequency (providing an inductive reactance component) and a smaller loop to resonate higher than the design frequency (introducing a capacitive-reactance component), causing the current to lead in the smaller loop and lag in the larger loop. The element lengths are 0.560 λ for the larger loop, and 0.508 λ for the smaller loop. According to the range tests performed by Maxwell, to achieve *optimum* circular polarization, the wire used in the construction of the bifilar elements should be 0.0088 λ in diameter.

Maxwell indicates that in the quadrifilar mode, the fields from the individual bifilar helices combine in optimum phase to obtain unidirectional end-fire gain. The currents in the two bifilars must be in quadrature phase. This 90° relationship is obtained by making their respective terminal impedances R $+jX$ and R $-jX$ where X = R, so that the currents in the respective helices are –45° and +45°. The critical parameter in this relationship is the terminal reactance, X, where the distributed inductance of the helical element is the primary determining factor. This assures the ±45° current relationship necessary to obtain true circular polarization in the combined fields and to obtain maximum forward radiation and minimum back lobe. Failure to achieve the optimum element diameter of 0.0088 λ results in a form of elliptical, rather than true circular polarization, and the performance may be a few tenths of a decibel below optimum, according to Maxwell's calculations. Using #10 wire translates roughly to an element diameter of 0.0012 λ at 137.5 MHz — not ideal, but good enough.

**Figure 55 — The antenna with two of the four legs (filars) of one loop attached.**

To get a grasp of the QHA's topography, visualize the antenna as consisting of two concentric cylinders over which the helices are wound (see **Figure 54** through **Figure 58**). In two-dimensional space, the cylinders

[2]M. W. Maxwell, W2DU, *Reflections III* (CQ Communications, 2010, **cq-amateur-radio.com**)
[3]R. Brickner Jr and H. Rickert, "An S-Band Resonant Quadrifilar Antenna for Satellite Communication," RCA Corp, AstroElectronics Div.

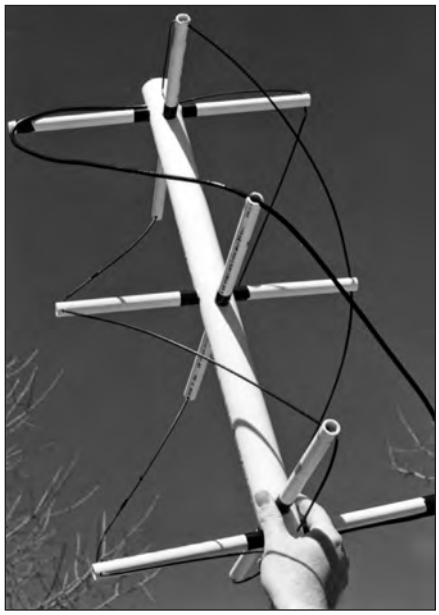

**Figure 56 — This view shows the QHA with all four legs in place. The ends of the PVC cross arms that hold the coaxial leg are notched; the wire elements pass through holes drilled in the ends of their supporting cross arms.**

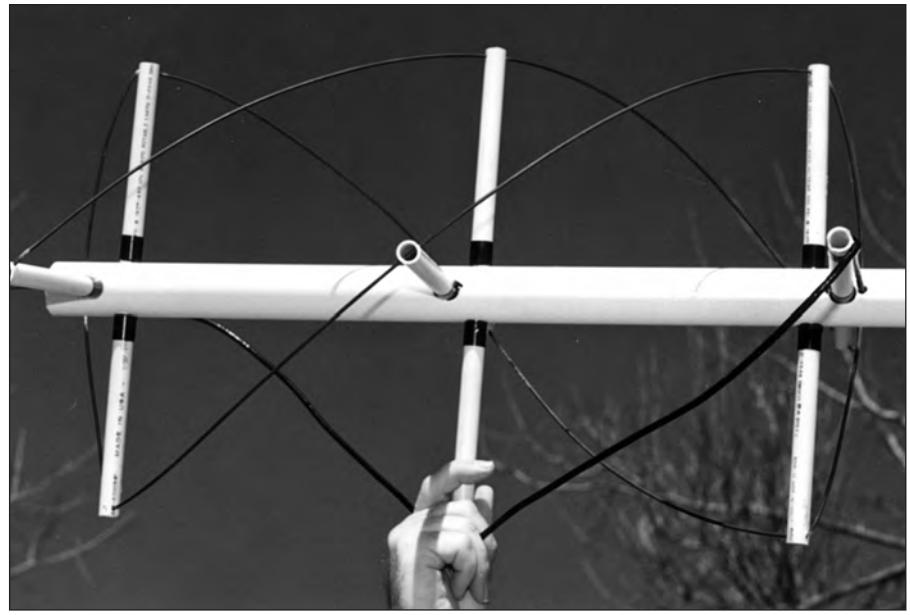

**Figure 57 — Another view of the QHA.**

**Figure 58 — An end-on view of the top of the QHA prior to soldering the loops and installing the PVC cap.**

can be represented by two nested rectangles depicting the height and width of the cylinders. The width of the larger cylinder (or rectangle) can be represented by 0.173 λ and the width of the smaller cylinder represented by 0.156 λ. The length of the larger cylinder or rectangle can be represented by 0.260 λ, and the length of the smaller rectangle or cylinder can be represented by 0.238 λ. Using these figures, you should be able to scale the QHA to virtually any frequency. **Table 6** shows some representative antenna sizes for various frequencies, along with the universal parameters needed to arrive at these figures.

## PHYSICAL CONSTRUCTION

**Figure 59** shows the construction details. A 25-inch-long piece of schedule 40, 2-inch-diameter PVC pipe is used for the vertical member. The cross arms that support the helices are six pieces of ½-inch-diameter PVC tubing: three the width of the large rectangle or cylinder, and three the width of the smaller cylinder. Two cross arms are needed for the top and bottom of each cylinder. The cross arms are oriented perpendicularly to the vertical member and parallel to each other. A third cross arm is placed midway between the two at a 90° angle. This process is repeated for the smaller cylindrical dimensions using the three smaller cross arms with the top and bottom pieces oriented 90° to the large pieces.

Using ⅝ inch-diameter holes in the 2-inch pipe ensures a reasonably snug fit for the ½-inch-diameter cross pieces. Each cross arm is drilled (or notched) at its ends to accept the lengths of wire and coax used for the elements. Then the cross arms are centered and cemented in place with PVC cement. For the 137 and 146 MHz antennas, use #10 AWG copper clad antenna wire for three of the helices and a length of RG-8 for the balun, which is also the fourth helix. (Do not consider the velocity factor of the coax leg for length calculation.) For the UHF antennas, use #10 AWG soft-drawn copper wire and RG-58 coax. Copper clad wire is difficult to work with, but holds its shape well. Smaller antennas can be built without the cross arms because the wire is sufficiently self-supporting.

To minimize confusion regarding the connections and to indicate the individual legs of the helices, label each loop or cylinder as B (for big) and S (for small); T and B indicate top and bottom. Each loop can be further split using leg designators as B1T and B1B, B2T and B2B, S1T and S1B and S2T and S2B, with B2 being the length of coax and the other three legs as wires. For righthand circular polarization (RHCP) wind the helices *counterclockwise* as viewed from the top. This is contrary to conventional axial mode

**Table 6**

helix construction. (For LHCP, the turns rotate *clockwise* as viewed from the top.) See **Figure 60** for the proper connections for the top view. When the antenna is completed, the view shows that there are two connections made to the center conductor of the coax (B2) top. These are B1T and S1T, for a total of three wires on one connection. S2T connects to B2T braid. The bottom of the antenna has S1B and S2B soldered together to complete the smaller loop. B1B and the braid of B2B are soldered together. Attach an SO-239 connector to the bottom by soldering the center conductor of B2B to the center of the connector and the braid of B2B to the connector's shell. The bottom now has two connections to the braid: one to leg B1B, the other to the shell of the connector. There's only one connection to the center conductor of B2B that goes to the SO-239 center pin.

Total price for all new materials-including the price of a suitable connector-should be in the neighborhood of $10 or less.

### RESULTS

With a 70-foot section of RG-9 between the receiver and antenna, which is mounted about 12 feet above ground, and a preamp in the shack the author receives fade-free passes from the weather satellites. Although the design indicates a 3-dB beamwidth of 140°, an overhead pass provides useful data down to 10° above the horizon. The 70 centimeter antenna works fine for PACSATs, although Doppler effect makes manual tracking difficult. The weather-satellite antenna prototype worked better than expected and a number of copies built by others required no significant changes.

Thanks to Chris Van Lint, and Tom Loebl, WA1VTA, for supplying technical data to complete this project, and to the late Walt Maxwell, W2DU, for his review and technical evaluation and for sharing his technical expertise with the amateur satellite community.

# 8 Earth-Moon-Earth (EME) Communication

EME communication, also known as *moonbounce*, has become a popular form of amateur space communication. The EME concept is simple: the Moon is used as a passive reflector for two-way communication between two locations on Earth (see **Figure 61**). With a total path length of about half a million miles, EME may be considered the ultimate DX. Very large path losses suggest big antennas, high power and the best low noise receivers; however, the adoption of modern coding and modulation techniques can significantly reduce these requirements from their 20th-century levels. Even so, communication over the EME path presents unusual station design challenges and offers special satisfaction to those who can meet them.

## 8.1 Background

EME is a natural and passive propagation phenomenon, and EME QSOs count toward WAC, WAS, DXCC, WAZ, and VUCC awards. EME opens up the bands at VHF and above to a new frontier of worldwide DX.

Professional demonstrations of EME capability were accomplished shortly after WW II. Amateurs were not far behind, with successful reception of EME echoes in 1953 and pioneering two-way contacts made on the 1296, 144, and 432 MHz bands in the 1960s. Increased EME activity and advances to other bands came in the 1970s, aided by the availability of reliable low-noise semiconductor devices and significant improvements in the design of Yagi arrays and feed antennas for parabolic dishes. These trends accelerated further in the 1980s with the advent of low-noise GaAsFET and HEMT preamplifiers and computer-aided antenna designs, and again after 2000 with the introduction of digital techniques. See the sidebar, "Amateur EME Milestones."

EME QSOs have been made on all amateur bands from 28 MHz to 47 GHz. Many operators have made WAC, WAS and even DXCC on one or more of the VHF and UHF bands. EME is now within the grasp of most serious VHF, UHF, and microwave operators.

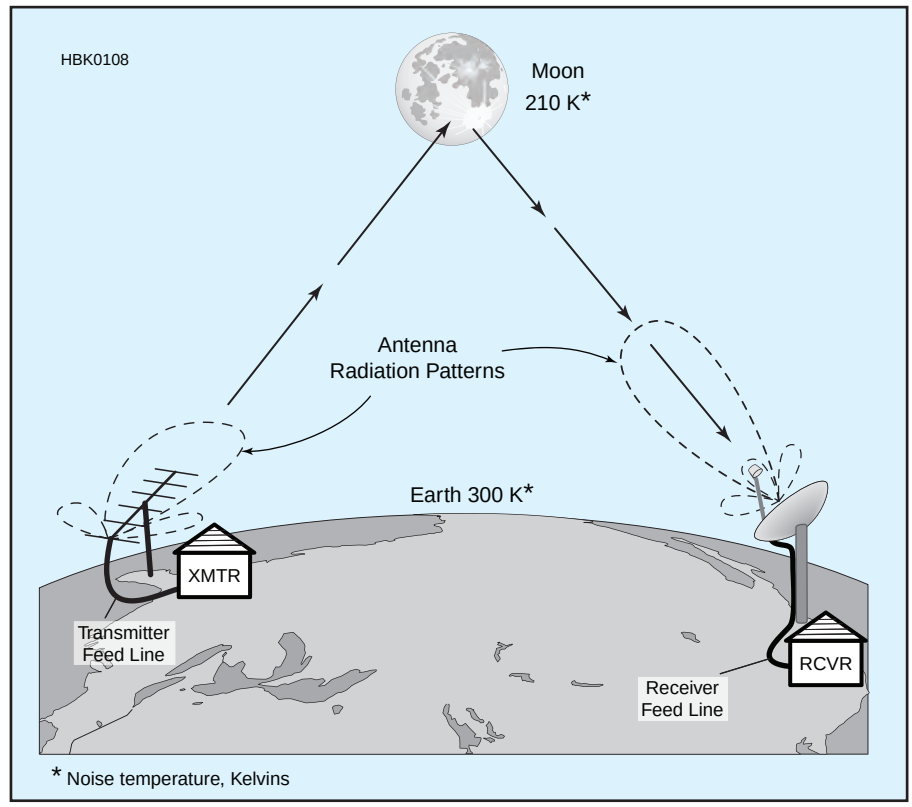

**Figure 61 — Schematic representation of major system components for a (one-way) EME path. This illustration also shows some of the factors contributing to system noise temperature, which is discussed later in the chapter.**

# 9 EME Propagation

## 9.1 Path Loss

Path loss in free space is caused by nothing more than the spherical expansion of a radio wave as it propagates away from an antenna. An EME signal is attenuated as $1/d^2$ (inverse distance squared) over the quarter-million mile path to the Moon, and again as $1/d^2$ on the return trip, for a net $1/d^4$ path loss. Radio waves incident on the surface of the Moon are often said to be "reflected," although in fact they are partly absorbed and partly scattered by the irregular lunar surface. A full expression giving the EME path loss as a ratio of received power to transmitted power, assuming isotropic antennas at each end of the path, is

$$\ell = \frac{\eta r^2 \lambda^2}{64 \pi^2 d^4} \qquad (1)$$

where

r is the radius of the Moon
λ is the wavelength
d is the distance to the Moon
η is the lunar reflection coefficient.

In this section we use the convention of lower-case letters to denote dimensionless ratios, and the corresponding upper-case letters to give equivalent values in dB. Thus, the EME path loss in dB is given for isotropic antennas by the expression

$$L = 10 \log \ell = 10 \log \left( \frac{\eta r^2 \lambda^2}{64 \pi^2 d^4} \right) \qquad (2)$$

Inserting values r = $1.738 \times 10^6$ m, d = $3.844 \times 10^8$ m and η = 0.065 gives the average path losses quoted in **Table 7** for the principal amateur EME bands. The need to overcome these very large attenuations is of course the main reason why EME is so challenging. The Moon's orbit is an ellipse, and its distance d varies by ±6.8% over each month. Because of the inverse-fourth-power law in Equations (1) and (2), this change results in path-loss variations of ±1.1 dB at the extremes of lunar distance, independent of frequency. The reflection of radio waves is of course not affected by the optical phases of the Moon.

The dependence of path loss on $l^2$ suggests that EME should be nearly 20 dB more difficult at 1296 MHz than at 144 MHz. This conclusion is misleading, however, because of the assumption of isotropic antennas. If one uses transmitting and receiving antennas of gain $g_t$ and $g_r$, expressed as ratios, the expected power $p_r$ received as a lunar echo may be written as the product

$$p_r = p_t g_t g_r \ell \qquad (3)$$

where $p_t$ is the transmitted power. The standard expression for an antenna's power gain is

$$g = 4\pi A / l^2$$

where A is the effective aperture or collecting area. Gain in dBi (dB over an isotropic antenna) may therefore be written as

$$G = 10 \log (4\pi A / l^2)$$

With $P_r$ and $P_t$ expressed in dB relative to some reference power, for example 1 W, we have

$$P_r = P_t + G_t + L + G_r \qquad (4)$$

Thus, assuming a fixed size of antenna, such as a parabolic dish or Yagi array of effective frontal area A, the frequency dependence is reversed: for a given transmitted power, lunar echoes would be 20 dB stronger for every decade increase in frequency, rather than 20 dB weaker. Most practical situations fall somewhere between these two extremes of frequency dependence.

For reasons explained in detail below, amateur EME communication is feasible with roughly comparable degrees of difficulty over nearly two decades of frequency, from 144 MHz to 10 GHz. Not surprisingly, some very different techniques must be mastered in order to do successful EME at the lower and upper extremes of this wide frequency range — so the final choice of band(s) for EME is often determined by the interests, skills and resources of an individual operator.

**Table 7**

**Two-Way EME Path Loss with Isotropic Antennas**

| *Frequency (MHz)* | *Average Path Loss (dB)* |
|---|---|

| 10368 | –289.2 |
| 24048 | –293.5 |

## 9.2 Echo Delay and Time Spread

Radio waves propagate at speed c, the speed of light, very nearly equal to $3 \times 10^8$ m/s. Propagation time to the Moon and back is therefore 2d/c or about 2.4 s at perigee, 2.7 s at apogee and 2.56 s on average. The Moon is nearly spherical, and its radius corresponds to r/c = 5.8 ms of wave travel time. The trailing parts of an echo, reflected from irregular surface features near the edge of the lunar disk, are delayed from the leading edge by as much as twice this value. In practice, most of the Moon's surface appears relatively smooth at the radio wavelengths used for amateur EME. Lunar reflections are therefore quasi-specular, like those from a shiny ball bearing, and the power useful for communication is mostly reflected from a small region near the center of the disk. At VHF and UHF frequencies, the effective *time spread* of an echo amounts to no more than 0.1 ms.

Reflection from a smooth surface preserves linear polarization and reverses the sense of circular polarization. At shorter wavelengths the lunar surface appears increasingly rough, so reflections at 10 GHz and above contain a significant diffuse component as well as a quasi-specular component. The diffuse component is depolarized, and significant portions of it arise from regions farther out toward the lunar rim. The median time spread can then be as much as several milliseconds. In all practical cases, however, time spreading is small enough that it does not cause significant smearing of CW keying or intersymbol interference in the slowly keyed modulations commonly used for digital EME.

Time spreading does have one very significant effect. Signal components reflected from different parts of the lunar surface travel different distances and arrive at Earth with random phase relationships. As the relative geometry of the transmitting station, receiving station and reflecting lunar surface changes, signal components may sometimes add and sometimes cancel, creating large amplitude fluctuations. Often referred to as *libration fading*, these amplitude variations will be well correlated over a *coherence bandwidth* of a few kHz, the inverse of the time spread.

## 9.3 Doppler Shift and Frequency Spread

EME signals are also affected by Doppler shifts caused by the relative motions of Earth and Moon. Received frequencies may be higher or lower than those transmitted; the shift is proportional to frequency and to the rate of change of total path length from transmitter to receiver. The velocities in question are usually dominated by the Earth's rotation, which at the equator amounts to about 460 m/s. For the self-echo or "radar" path, frequency shift will be maximum and positive

at moonrise, falling through zero as the Moon crosses the local meridian (north-south line) and a maximum negative value at moonset. The magnitude of shifts depends on station latitude, the declination of the Moon and other geometrical factors. For two stations at different geographic locations the mutual Doppler shift is the sum of the individual (one-way) shifts. Maximum values are around 440 Hz at 144 MHz, 4 kHz at 1296 MHz and 30 kHz at 10 GHz. (See the article by Al Katz, K2UYH, "Devilish Doppler" in the online supplemental material for more information on Doppler shift and its effect on EME communications.)

Just as different reflection points on the lunar surface produce different time delays, they also produce different Doppler shifts. The Moon's rotation and orbital motion are synchronized so that approximately the same face is always toward Earth. The orbit is eccentric, so the orbital speed varies; since the rotation rate does not vary, an observer on Earth sees an apparent slow "rocking" of the Moon, back and forth.

Further aspect changes are caused by the 5.1° inclination between the orbital planes of Earth and Moon. The resulting total line-of-sight velocity differences are around 0.2 m/s, causing a *frequency spread* of order 0.2 Hz at 144 MHz. Like all Doppler effects, these shifts scale with frequency. However, measured values of frequency spread increase slightly more rapidly than frequency to the first power because a larger portion of the lunar surface contributes significantly to echo power at higher frequencies. Linear scaling would suggest frequency spread around 15 Hz at 10 GHz, but measurements show it to be several times larger.

From a communication engineering point of view, libration fading is just another example of the so-called *Rayleigh fading* observed on any radio channel that involves multiple signal paths — such as ionospheric skywave, tropospheric scatter and terrain multipath channels with reflections from buildings, trees or mountains. Interference effects that cause signal fading depend on frequency spread as well as time spread. Signal amplitudes remain nearly constant over a *coherence time* given by the inverse of frequency spread. In general, fading rates are highest (shortest coherence times) when the Moon is close to the local meridian and lowest near moonrise and moonset. They also depend on the Moon's location in its elliptical orbit.

Typical coherence times are several seconds at 144 MHz, a few tenths of a second at 1296 MHz and 20 ms at 10 GHz. At 144 MHz, intensity peaks lasting a few seconds can aid copy of several successive CW characters, but at 432 MHz the timescale of peaks and dropouts is closer to that of single characters. At 1296 MHz the fading rates are often such that CW characters are severely chopped up, with dashes seemingly converted to several dits; while the extremely rapid fading at 10 GHz can give signals an almost "auroral" tone. Skilled operators must learn to deal with such effects as best they can. As described further below, modern digital techniques can use message synchronization as well as error-correcting codes and other diversity techniques to substantially improve the reliability of copy on marginal, rapidly fading EME signals.

## 9.4 Atmospheric and Ionospheric Effects

Propagation losses in the Earth's troposphere are negligible at VHF and UHF, although rain attenuation can be an important factor above 5 GHz. Tropospheric ducting of the sort that produces enhanced terrestrial propagation can bend signals so that the optimum beam heading for EME is directed away from the Moon's center. Even under normal conditions, enough refraction occurs to allow radio echoes when the Moon is slightly below the visible horizon. In practice, these problems are usually overshadowed by other complications of doing EME at very low elevations, such as blockage from nearby trees or buildings, increased noise from the warm Earth in the antenna's main beam and man-made interference.

The Earth's ionosphere causes several propagation effects that can be important to EME. These phenomena depend on slant distance through the ionospheric layer, which increases at low elevations. At elevation 10°, attenuation through the daytime ionosphere is generally less than 0.5 dB at 144 MHz, and nighttime values are at least 10 times lower. These numbers scale inversely as frequency squared, so ionospheric absorption is mostly negligible for EME purposes. Exceptions can occur at 50 MHz, and under disturbed ionospheric conditions at higher frequencies. Ionospheric refraction can also be important at 50 MHz, at very low elevations. Ionospheric scintillations (analogous to the "twinkling" of stars in the Earth's atmosphere) can exhibit significant effects at VHF and UHF, primarily on EME paths penetrating the nighttime geomagnetic equatorial zone or the auroral regions. Again, disturbed ionospheric conditions magnify the effects. The multipath time spread is very small, less than a microsecond, while frequency spread and fading rate can be in the fractional hertz to several hertz range. These scintillations can increase the fading rates produced by Earth rotation and lunar librations.

Much more important is the effect of Faraday rotation in the ionosphere. A linearly polarized wave will see its plane of polarization rotate in proportion to the local free-electron density, the line-of-sight component of the Earth's magnetic field and the square of wavelength. The effect is therefore greatest during the daytime, for stations well away from the equator, and at low frequencies. A mismatch $D\theta$ between an incoming wave's polarization angle and that of the receiving antenna will attenuate received signal power by an amount $\cos^2 D\theta$. As shown in **Figure 62**, polarization losses increase rapidly when the misalignment exceeds 45°.

Because of the $l^2$ dependence, Faraday rotation is generally important for EME operation only at 432 MHz and below. The effect is cumulative for an outgoing signal and its returning echo, so a station transmitting and receiving with the same linearly polarized antenna will see its own echoes disappear whenever the total Faraday rotation is close to an odd integral multiple of 90°. Faraday rotation in the daytime ionosphere can amount to as much as a full turn at 432 MHz and many turns at 144 MHz. At 432 MHz the rotation may be essentially constant over several hours; on lower bands significant changes can occur in 30 minutes or less. Variations are especially noticeable near sunrise or sunset at one end of the path, where ionization levels are changing rapidly.

The Earth's spherical shape determines the orientation in space of a wave emitted or received by an antenna with horizontal (or other locally referenced) polarization angle. As discussed in detail below, when combined with Faraday rotation this effect can cause users of fixed-linear-polarization antennas to experience apparent one-way propagation.

A polarized radio signal reflected from the Moon's rough surface is partially scattered into other polarization states, and a disturbed ionosphere can sometimes generate a mixture of polarization angles. As a consequence, fading caused by 90° polarization misalign-

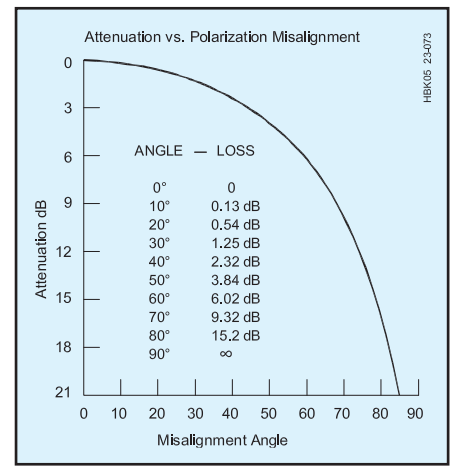

**Figure 62 — Attenuation caused by misalignment of a linearly polarized signal with the polarization angle of a receiving antenna. The attenuation increases rapidly for alignment errors greater than 45°.**

ments will not always produce deep nulls. Measurements show that at UHF and below, the cross-polarized scattered signal is usually 15 dB or more below the principal polarization. On the other hand, at 10 GHz and higher, where the lunar surface is much rougher in terms of wavelength, cross-polarized diffuse echoes may be only a few dB below the principal reflected polarization. These comments apply to both linear and circular polarization.

# 10 Fundamental Limits

## 10.1 Background Noise

EME signals are always weak, so considerations of signal-to-noise ratio are paramount. (Noise is also discussed in the **RF Techniques** chapter.) A received signal necessarily competes with noise generated in the receiver as well as that picked up by the antenna, including contributions from the warm Earth, the atmosphere, the lunar surface, the diffuse galactic and cosmic background and possibly the sun and other sources. (Refer to Figure 61, and think of adding a warm atmosphere just above the Earth, the sun somewhere beyond the Moon, and galactic and extragalactic noise sources at even greater distances, filling the whole sky.)If $P_n$ is the total noise power collected from all such noise sources expressed in dBW, we can write the expected signal-to-noise ratio of the EME link as

$$SNR = P_r - P_n = P_t + G_t + L + G_r - P_n \quad (5)$$

Since isotropic path loss L is essentially fixed by choice of a frequency band (Table 7), optimizing the signal-to-noise ratio generally involves trade-offs designed to maximize $P_r$ and minimize $P_n$ — subject, of course, to such practical considerations as cost, size, maintainability and licensing constraints.

It is convenient to express $P_n$ (in dBW) in terms of an equivalent system noise temperature $T_s$ in kelvins (K), the receiver bandwidth B in Hz and Boltzmann's constant k = 1.38 × $10^{-23}$ J $K^{-1}$:

$$P_n = 10 \log (kT_sB) \quad (6)$$

The system noise temperature may in turn be written as

$$T_s = T_r + T_a \quad (7)$$

Here $T_r$ is receiver noise temperature, related to the commonly quoted noise figure (NF) in dB by

$$T_r = 290 (10^{0.1NF} - 1) \quad (8)$$

Antenna temperature $T_a$ includes contributions from all noise sources in the field of view, weighted by the antenna pattern. The lunar surface has a temperature around 210 K; since most antennas used for amateur EME have beamwidths greater than the

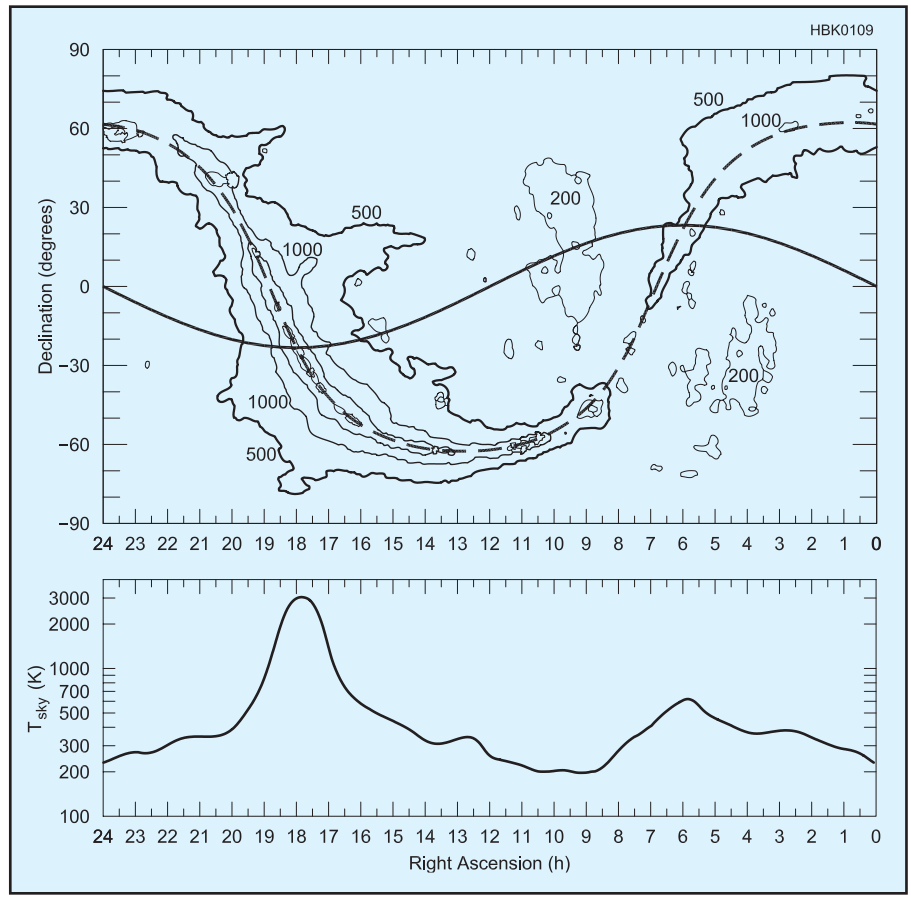

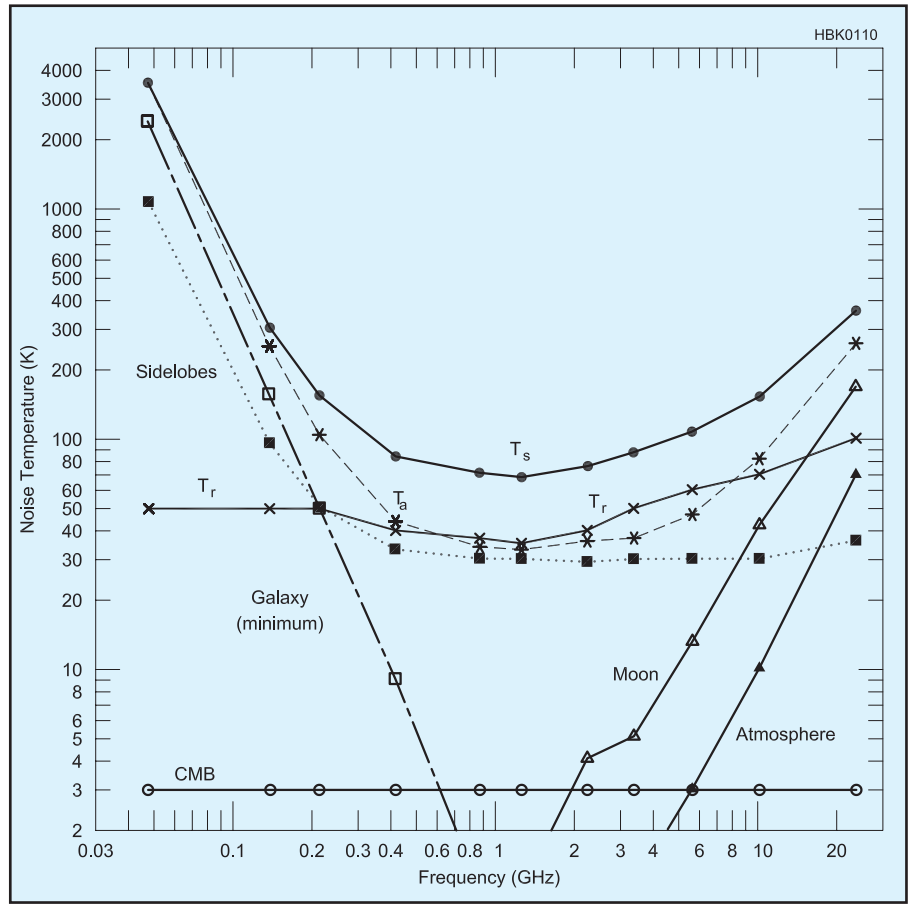

**Figure 63 — *Top:* All-sky contour map of sky background temperature at 144 MHz. The dashed curve indicates the plane of our Galaxy, the Milky Way; the solid sinusoidal curve is the plane of the ecliptic. The Sun follows a path along the ecliptic in one year; the Moon moves approximately along the ecliptic (± 5°) each month. Map contours are at noise temperatures 200, 500, 1000, 2000 and 5000 K. *Bottom:* One-dimensional plot of sky background temperature at 144 MHz along the ecliptic, smoothed to an effective beamwidth 15°.**

**Figure 64 — Typical contributions to system noise temperature $T_s$ as function of frequency. See text for definitions and descriptions of the various sources of noise.**

Moon's angular size, as well as sidelobes, the Moon's effect will be diluted and noise from other sources will also be received. Sidelobes are important, even if many dB down from the main beam, because their total solid angle is large and therefore they are capable of collecting significant unwanted noise power.

At VHF the most important noise source is diffuse background radiation from our Galaxy, the Milky Way. An all-sky map of noise temperature at 144 MHz is presented in the top panel of **Figure 63**. This noise is strongest along the plane of the Galaxy and toward the galactic center. Galactic noise scales as frequency to the –2.6 power, so at 50 MHz the temperatures in Figure 63 should be multiplied by about 15, and at 432 divided by 17. At 1296 MHz and above galactic noise is negligible in most directions. During each month the Moon follows a right-to-left path lying close to the ecliptic, the smooth solid curve plotted in Figure 63. Sky background temperature behind the Moon therefore varies approximately as shown in the lower panel of Figure 63, regardless of geographical location on Earth. For about five days each month, when the Moon is near right ascension 18 hours and declination –28°, VHF sky background temperatures near the Moon are as much as 10 times their average value, and conditions for EME on the VHF bands are poor.

By definition the Sun also appears to an observer on Earth to move along the ecliptic, and during the day solar noise can add significantly to $P_n$ if the Moon is close to the sun or the antenna has pronounced sidelobes. At frequencies greater than about 5 GHz the Earth's atmosphere also contributes significantly. An ultimate noise floor of 3 K, independent of frequency, is set by cosmic background radiation that fills all space. A practical summary of significant contributions to system noise temperature for the amateur bands 50 MHz through 24 GHz is presented in **Table 8** and **Figure 64** and **Figure 65**, discussed in the next section.

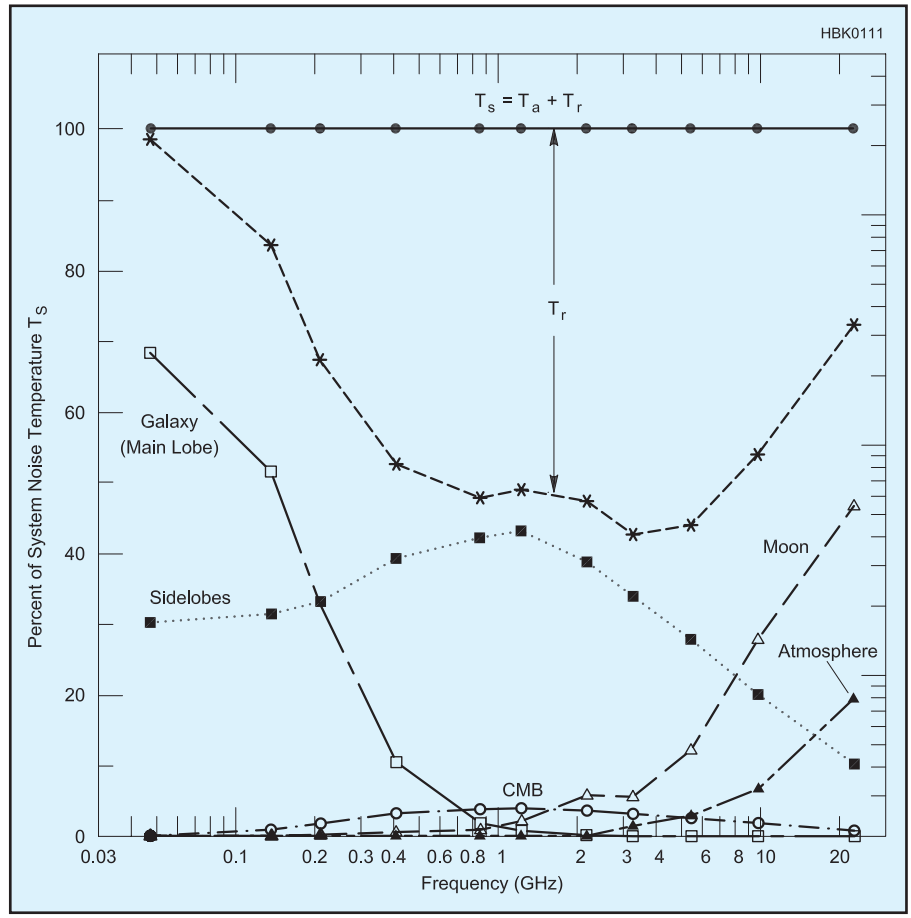

**Figure 65 — Percentage contributions to system noise temperature as a function of frequency.**

## 10.2 Antenna and Power Requirements

The basic circumstances described so far ensure that frequencies from 100 MHz to 10 GHz are the optimum choices for EME and space communication. Over this region and a bit beyond, a wide variety of propagation effects and equipment requirements provide a fascinating array of challenges and opportunities for the EME enthusiast. The enormous path-loss variability encountered in terrestrial HF and VHF propagation does not occur in EME work, and some of the remaining, smaller variations — for example, those arising from changing lunar distance and different sky background temperatures — are predictable. We can therefore estimate with some confidence the minimum antenna sizes and transmitter powers required for EME communication on each amateur band.

The necessary information for this task is summarized in Table 8 and Figures 64 and 65. Columns 2 through 6 of the table give typical contributions to system noise temperature from the cosmic microwave background (CMB), the Earth's atmosphere, the warm surface of the Moon, galactic noise entering through the main antenna beam and sky and ground noise from an antenna's side and rear lobes. Antenna temperature $T_a$ is a combination of all these contributions, appropriately weighted by antenna pattern; the system noise temperature $T_s$ is then the sum of $T_a$ and receiver noise temperature $T_r$, referred to the antenna terminals. Numbers in Table 8 are based on the fundamentals described in the previous section and on hypothetical antennas and receivers that conform to good amateur practice in the year 2009; they have been rounded to two significant figures. It is possible to do slightly better than these numbers — for example, by building antennas with lower sidelobe response or preamplifiers with still lower noise figure — but it's not easy!

The topmost curve in Figure 64 illustrates clearly why the frequency range from 100 MHz to 10 GHz is optimum for EME communication. Figure 65 shows that further reductions of $T_s$ must come from lower $T_r$ or better suppression of antenna sidelobes. There is nothing you can do about noise from the CMB, atmosphere, Moon or Galaxy entering your main beam! For comparison, the very best professional receiving equipment achieves system noise temperatures around 20 K in the 1-2 GHz region — only a few dB better than current amateur practice. These systems generally use cryogenic receivers and very large dish antennas that can provide better suppression of sidelobes.

Having established reasonable target figures for system noise temperature, we can now proceed to estimate minimum antenna and power requirements for an EME-capable station on each amateur band. Rearrangement of Equations (5) and (6) yields the following relation for transmitter power $P_t$ in dBW:

$$P_t = SNR - G_t - G_r - L + 10 \log (kT_sB) \quad (9)$$

Values for L and $T_s$ can be taken for each amateur band from Tables 7 and 8. For illustrative purposes let's assume SNR = 3 dB and B = 50 Hz, values appropriate for a good human operator copying a marginal CW signal. (The 50 Hz effective bandwidth may be established by an actual hardware or software filter, or more commonly by the operator's "ear-and-brain" filter used toget her with a broader filter in the transceiver.) For antennas we shall assume bays of four long Yagis for the 50 through 432 MHz bands, parabolic dishes of diameter 3 m on 1296 and 2304 MHz and 2 m dishes on the higher bands. Representative gains and half-power beamwidths for such antennas are listed in columns 3 and 4 of **Table 9**. Column 5 then gives the necessary transmitter power in watts, rounded to two significant figures.

**Figure 66 — The 12-element Yagi used by DL1VPL to complete DXCC on 144 MHz.**

A station with these baseline capabilities should be self sufficient in terms of its ability to overcome EME path losses — and thus able to hear its own EME echoes and make CW contacts with other similarly equipped EME stations. Note that the quoted minimum values of transmitter power do not allow for feed line losses; moreover, a CW signal with SNR = 3 dB in 50 Hz bandwidth hardly represents "armchair copy." At the highest frequencies, issues of oscillator stability and Doppler spreading might make the assumed 50 Hz bandwidth unrealistically narrow, thus requiring somewhat more power or a larger antenna. On the other hand, lower power and smaller antennas can be sufficient for working stations with greater capabilities than those in the table.

Other factors can reduce the minimum power or antenna gains required for successful EME, at least some of the time. One possibility, especially effective at 50 and 144 MHz at low moon elevations, is to take advantage of reflections from reasonably smooth ground (or better still, water) in front of your antenna. Often referred to as *ground gain*, these reflections can add as much as 6 dB to an antenna's effective gain at elevations where the reflections are in phase with the direct signal. Another possibility is to use more efficient coding and modulation schemes than provided by Morse coded CW.

**Table 9**
**Typical Antenna and Power Requirements for CW EME**

| *Freq (MHz)* | *Ant Type[1]* | *G (dBi)* | *HPBW (deg)* | *TxPwr (W)* |
|---|---|---|---|---|
| 50 | 4×12 m | 19.7 | 18.8 | 1200 |
| 144 | 4×6 m | 21.0 | 15.4 | 500 |
| 432 | 4×6 m | 25.0 | 10.5 | 250 |
| 1296 | 3 m | 29.5 | 5.5 | 160 |
| 2304 | 3 m | 34.5 | 3.1 | 60 |
| 3456 | 2 m | 34.8 | 3.0 | 120 |
| 5760 | 2 m | 39.2 | 1.8 | 60 |
| 10368 | 2 m | 44.3 | 1.0 | 25 |

[1]Example antennas for 50, 144 and 432 MHz are Yagi arrays with stated lengths; those for 1296 MHz and higher are parabolic dishes of specified diameter.

## 10.3 Coding and Modulation

International Morse code with on-off keying (OOK) is an excellent general purpose communication mode. It is easy to implement and performs well in weak-signal conditions. EME operating procedures for CW usually include multiple repetitions so that essential parts of a bare-minimum QSO can be assembled from fragments copied on signal peaks. However, modern communication theory

points the way toward modulation schemes significantly more efficient than OOK, codes better than Morse, and error-control methods more effective than simple repetition. Amateur experiments with these ideas have led to the current popularity of digital EME on the VHF, UHF, and microwave bands. In general, an efficient digital mode designed for basic communication with weak signals will compress user messages into a compact form and then add redundancy in the form of a mathematically defined error-correcting code (ECC). Such codes can ensure that full messages are recoverable with high confidence, even when significant portions of a transmission are lost or corrupted.

A number of distinct sources may contribute to the improved performance of such a mode over CW. Multitone FSK (MFSK) is a more efficient modulation than OOK, in part because each received symbol is roughly the equivalent of a full character, rather than a single dot or dash. For equivalent messages, MFSK can therefore be keyed much more slowly than CW and detected in a much smaller bandwidth. Morse code is self-synchronizing at the character level (if a signal is strong enough for letters to be recognized), but a Morse transmission contains no useful information for synchronizing a whole message. This fact makes it difficult to piece together copied fragments of a CW message being sent repeatedly. As discussed later in the Operating Procedures section, K1JT's software package *WSJT-X* includes several MFSK modes for low SNR communications on HF and VHF/UHF/microwaves. More information is available in the **Digital Protocols and Modes** chapter and at **physics.princeton.edu/pulsar/k1jt/wsjt.html**. Also see the sidebar later in this chapter, "Computing and Internet Resources for EME."

In contrast, a synchronized digital transmission with ECC can encode the complete message into a new data format designed to enhance the probability that successful decoding will produce the message's full information content, with everything in its proper place. For the limited purpose of exchanging call signs, signal reports and modest amounts of additional information, digital EME contacts can be made at signal levels some 10 dB below those required for CW, while at the same time improving reliability and maintaining comparable or better rates of information throughput. Depending on your skill as a CW operator, the digital advantage may be even larger.

Thus, digital EME contacts are possible between similar stations with about 10 dB less power than specified in Table 9, or with 5 dB smaller antenna gains at both transmitter and receiver. Examples of antennas for three small but very effective EME stations are shown in **Figures 66** to **68**. Figure 66 shows the single 12-element Yagi used by Thomas, DL1VPL, to complete his DXCC on 144 MHz. Figure 67 shows the highly portable EME setup of Bodo, DL3OCH. With a single long Yagi (59 elements, 5 m boom, 21.8 dBi gain), a 100 W solid state power amplifier (SSPA) and the JT65C digital mode,[1] this equipment has helped him to provide dozens of new DXCC credits on 1296 MHz from countries with little or no regular EME activity. Figure 68 shows the 10 GHz portable station of Rex, VK7MO. It includes a 10 GHz transverter, a 50 W SSPA, and a 2.5-foot (75 cm) dish mounted on a collapsible tripod. Rex has made hundreds of EME contacts with this equipment using the JT4 and QRA64 digital modes.

**Figure 67 — TF/DL3OCH used a rural road sign to help him give contacts with Iceland to a number of EME operators on 1296 MHz. Bodo has activated many DXCC entities on 1296 MHz EME by using JT65, a single long Yagi and a 100 W solid state amplifier.**

**Figure 68 — The portable EME-capable 10 GHz station of VK7MO, set up at roadside in the Australian outback.**

# 11 Building an EME Station

## 11.1 Antennas

The antenna is arguably the most important element in determining an EME station's capability. It is not accidental that the baseline station requirements outlined in Table 9 use Yagi arrays on the VHF bands and parabolic dishes at 1296 MHz and above: one of these two antenna types is almost always the best choice for EME. The gain of a modern, well designed Yagi of length $\ell$ can be approximated by the equation

$$G = 8.1 \log (\ell / \lambda) + 11.4 \text{ dBi} \qquad (10)$$

and stacks of Yagis can yield close to 3 dB (minus phasing line losses) for each doubling of the number of Yagis in the stack.

For comparison, the gain of a parabolic dish of diameter d with a typical feed arrangement yielding 55% efficiency is

$$G = 20 \log (d/\lambda) + 7.3 \text{ dB} \qquad (11)$$

The gains of some nominal antennas of each type are illustrated graphically in **Figure 69**, which helps to show why Yagis are nearly always the best choice for EME on the VHF bands. They are light, easy to build and have relatively low wind resistance. Stacks of four Yagis are small enough that they can

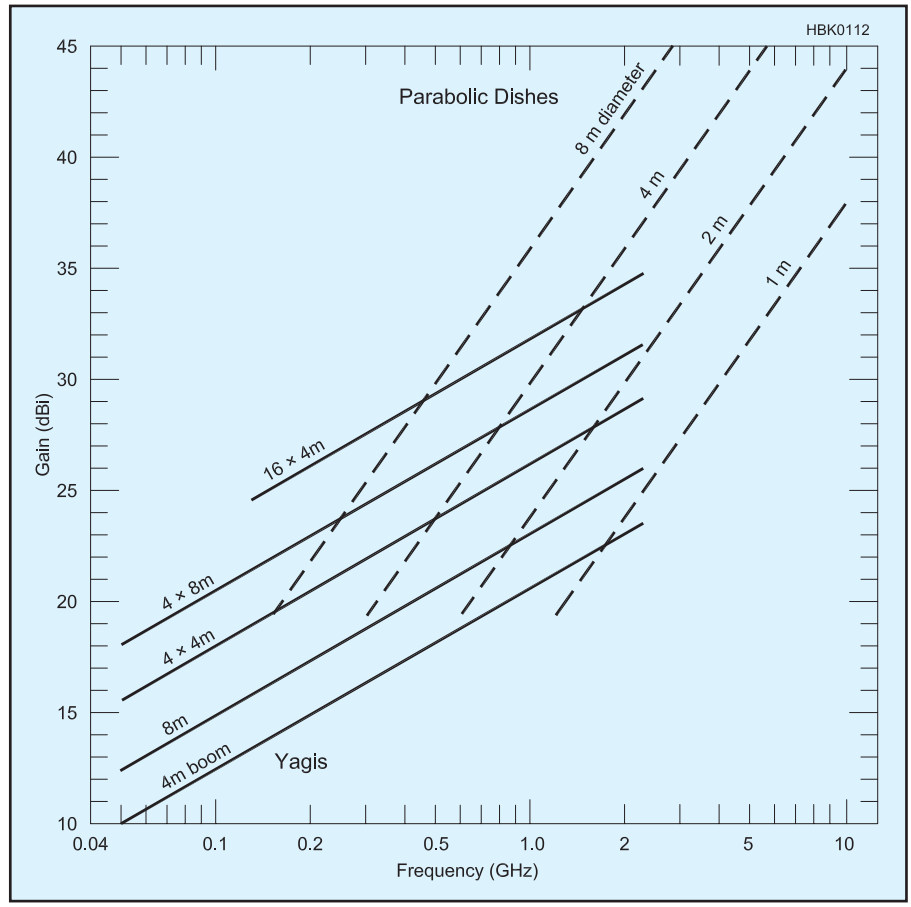

**Figure 69 — Representative gains of practical Yagi antennas, arrays of Yagis and parabolic dishes as a function of frequency. Yagi arrays make the most cost-effective and convenient antennas for EME on the VHF bands, while parabolic dishes are generally the best choice above 1 GHz.**

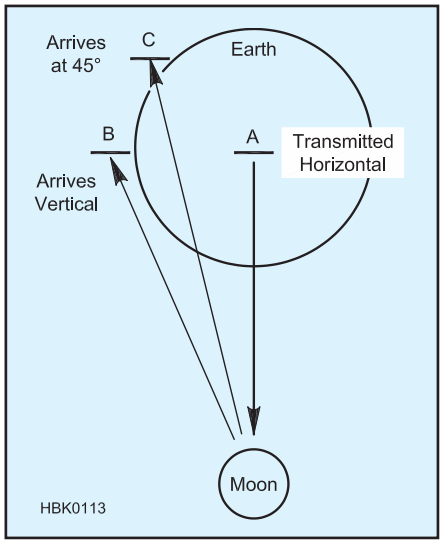

**Figure 70 — The spherical Earth creates spatial polarization offsets for well-separated stations with horizon-oriented linear polarization. Here, a signal transmitted horizontally at A arrived with vertical polarization at B and midway between horizontal and vertical at C. When combined with Faraday rotation, offsets close to 45° can lead to apparent one-way propagation. See text for details.**

**Figure 71 — Array of four 10-element, dual-polarization 144 MHz Yagis at KL7UW. Alaskan frost makes the horizontal and vertical elements stand out clearly. A pair of loop Yagis for 1296 MHz can be seen inside the 2 meter array.**

**Figure 72 — Dual-polarization EME array at W2PU. At the left, shows the four 15-element, rear-mounted Yagis. Boom length is 3.5 m, and stacking distance is 1.2 m in each direction. The right photo is a close-up showing some details around the driven loops.**

be mounted on towers for sky coverage free of nearby obstructions. Larger arrays of 8, 16 or even more Yagis are possible, although the complexity and losses in phasing lines and power dividers then become important considerations, especially at higher frequencies. Long Yagis are narrowband antennas, usable on just a single band.

We usually think of the linear polarization of a transmitted signal as being "horizontal" or "vertical." Of course, on the spherical Earth these concepts have meaning only locally. As seen from the Moon, widely separated horizontal antennas may have very different orientations (see **Figure 70**). Therefore, in the absence of Faraday rotation an EME signal transmitted with horizontal polarization by station A will have its linear polarization misaligned at stations B and C by angles known as the *spatial polarization offset*. In Figure 70 the signal from A arrives with vertical polarization at B and at 45° to the horizon at C. Suppose C is trying to work A and $q_s$ = 45° is the spatial polarization offset from A to C. The return signal from C to A will be offset in the opposite direction, that is, by an amount $-q_s = -45°$. The Faraday rotation angle $\theta_F$, on the other hand, has the same sign for transmission in both directions. Thus the net polarization shift from A to C is $\theta_F + q_s$, while that from C to A is $\theta_F - q_s$. If $\theta_F$ is close to any of the values ±45°, ±135°, ±225°, …, then one of the net polarization shifts is nearly 90° while the other is close to 0°. The result for stations with fixed linear polarization will be apparent one-way propagation: for example, A can copy C, but C cannot copy A.

Obviously no two-way contact can be made under these conditions, so the operators must wait for more favorable circumstances or else implement some form of polarization control or polarization diversity. One cost-effective solution is to mount two full sets of Yagi elements at right angles on the same boom. Arrays of such cross-polarized or "Xpol" Yagis make especially attractive EME antennas on the VHF and lower UHF bands because they offer a flexible solution to the linear-polarization misalignment problem. As an example, **Figure 71** shows the 4 × 10 element, dual-polarization EME array at KL7UW. This antenna has accounted for many hundreds of EME contacts with the state of Alaska on 2 meters.

At 1296 MHz and above, gains of 30 dBi and more can be achieved with parabolic dishes of modest size. As a result, these antennas are almost always the best choice on these bands. Their structure does not depend on any radio frequency resonances, so in many ways dishes are less critical to build than Yagis. Element lengths in high-gain Yagis must be accurate to better than 0.005 λ, while the reflecting surface of a dish need be accurate only to about 0.1 λ. Mesh surfaces are attractive at frequencies up to at least 5 GHz, because of their light weight and lower wind resistance. Openings in the mesh can be as large as 0.05 λ without allowing much ground noise to feed through the surface. A parabolic antenna has a single feed point, so there are no losses in phasing lines or power splitters. You can use a dish on several bands by swapping feeds, and with suitable feed designs you can produce either linear or circular polarization, including dual polarizations. A very attractive and convenient option is to transmit in one sense of circular polarization and receive in the opposite sense. Transmitting in right-hand circular (RHC) and receiving in LHC has become the standard for EME on bands from 1296 MHz up to 5.7 GHz. Linear polarization is still used most commonly for EME at 10 and 24 GHz.

As made clear in Figure 69, the 432 MHz band lies in a transition region where both Yagis and parabolic dishes have attractive features. Either four long Yagis or a 6 m dish can produce enough gain (about 25 dBi) to let you work many other EME stations on this band. Many linear-polarization systems are already in use — for good reason, since most amateur use of this band is for terrestrial communication — so converting everyone to circular polarization is impractical. Therefore, schemes have been devised to physically rotate dish feeds and even whole Yagi arrays to cope with the resulting polarization alignment problems. Another scheme is to use a dual-polarization dish feed or dual-polarization Yagis, as described above and increasingly used on 144 MHz. This approach has not gained wide popularity on 432 MHz, mainly because at this wavelength it is hard to find room for the feedlines and matching system at the antenna feed points. One successful implementation is shown in **Figure 72**.

### ANTENNA PATTERN

A clean pattern with good suppression of side and rear lobes is important for all EME antennas — especially at 432 MHz and above, where excessive noise pickup through sid-

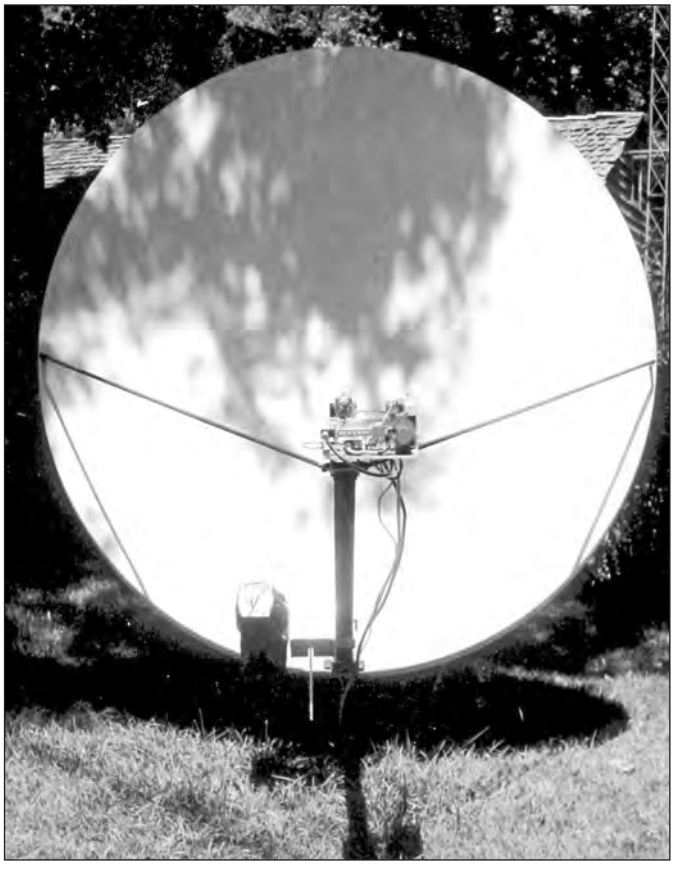

**Figure 73 — This 3 meter TVRO dish with aluminum frame and mesh surface was outfitted for 1296 MHz EME as a joint effort by VA7MM and VE7CNF. The dual-circular polarization feed is a VE4MA/W2IMU design.**

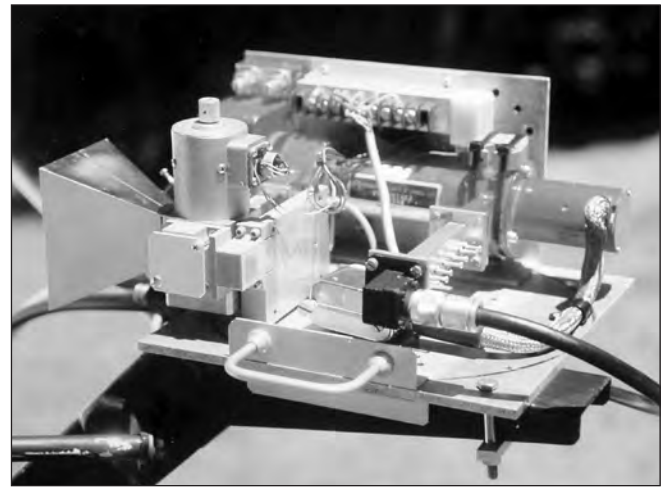
**Figure 74 — Mounting arrangement, counterweights and az/el control system for the VA7MM 3 meter dish.**



elobes can significantly increase $T_s$. For Yagi arrays you should use modern, computer-optimized designs that maximize $G/T_s$, the ratio of forward gain to system noise temperature. Be sure to pay attention to maintaining a clean pattern when stacking multiple antennas. First sidelobes within 10-15° of the main beam may not be a major problem, because their solid angle is small and they will look mostly at cold sky when EME conditions are favorable. Side and rear lobes farther from the main beam should be suppressed as much as possible, however. Remember that even close-in sidelobes will degrade your receiving performance at low elevations.

For parabolic dishes, $G/T_s$ is optimized by using a feed with somewhat larger taper in illumination at the edge of the dish than would yield the highest forward gain. Best forward gain is generally obtained with edge taper

**(A)**

**Figure 75 — N4MW outfitted this 2.6 m offset parabolic dish for 10 GHz EME. Equipment mounted at the focus (close-up at B) includes low noise preamplifier, transverter, traveling wave tube (TWT) power amplifier and feed horn for 10 GHz.**

**(B)**

around −10 dB, while best $G/T_s$ occurs around −15 dB. Edge taper of −12 dB is usually a good compromise. Some good reproducible designs for dish feeds are described in references at the end of this section.[2]

### ANTENNA MOUNTS

EME antennas have high gain and narrow main beams that must be properly aimed at the Moon in two coordinates. Although polar mounts (one axis parallel to the Earth's axis) have sometimes been used, by far the most popular mounting scheme today is the elevation-over-azimuth or *az/el* mount. Readily available computer software (see the sidebar, "Computer and Internet Resources for EME") can provide azimuth and elevation coordinates for the Moon, and a small computer can also control antenna positioning motors to automate the whole pointing system.

For mechanical reasons it is desirable to place the antenna's center of gravity close to the intersection of the vertical (azimuth) and horizontal (elevation) axes. On the other hand, the mounting structure must not interfere with critical active regions of the antenna. Stacked Yagis are generally mounted so that metallic supporting members are perpendicular to the radiating elements or located at midpoints where the effective apertures of separate Yagis meet. Feed lines and conducting support members must not lie in the active planes containing Yagi elements, unless they run wholly along the boom. For dual-polarization Yagis, feed lines should be routed toward the rear of each Yagi and any mid-boom support members must be non-conducting. For EME there is nothing magical about using horizontal and vertical for the two orthogonal polarizations, and there are some advantages to mounting cross-Yagis with elements in the "×" rather than "+" orientation.[3]

Parabolic dishes are usually mounted from behind, with counterweights extending rearward to relieve torque imbalance on the elevation axis. Screw-jack actuators designed for positioning 1980s-style TVRO dishes can be readily adapted for elevation control.[4] Standard heavy-duty antenna rotators can be used for azimuth positioning of dishes up to about 3 m in size. Larger dishes may require heavier, one-of-a-kind designs for pointing control. **Figures 73** through **75** show examples of parabolic dishes in the 2-3 m range, neatly and successfully outfitted for EME at VA7MM and N4MW.

## 11.2 Feed lines, Preamplifiers and TR Switching

Any feed line between the antenna and receiver introduces attenuation and noise, so at UHF and above it is vital that the low-noise preamplifier (LNA) be mounted very close to the antenna terminals. At ambient temperature, every 0.1 dB of loss in front of the LNA adds at least 7 K to the effective $T_r$, and therefore to $T_s$. On bands where $T_a$ is much lower than ambient, even 0.1 dB of attenuation can result in 0.5 dB loss of receiver sensitivity.

LNA gain should be sufficient to overcome feed line losses and dominate the noise contributed by subsequent stages by at least 15-20 dB. Current practices usually employ one or, especially at 432 MHz and above, two low-noise GaAsFET or HEMT transistors in the preamplifier, with only a simple noise impedance matching circuit between the first active device and the antenna. Only if severe out-of-band interference is present should a narrow filter be placed ahead of the first LNA. Bandpass filtering is often desirable between LNA stages, and may be used without signifi-

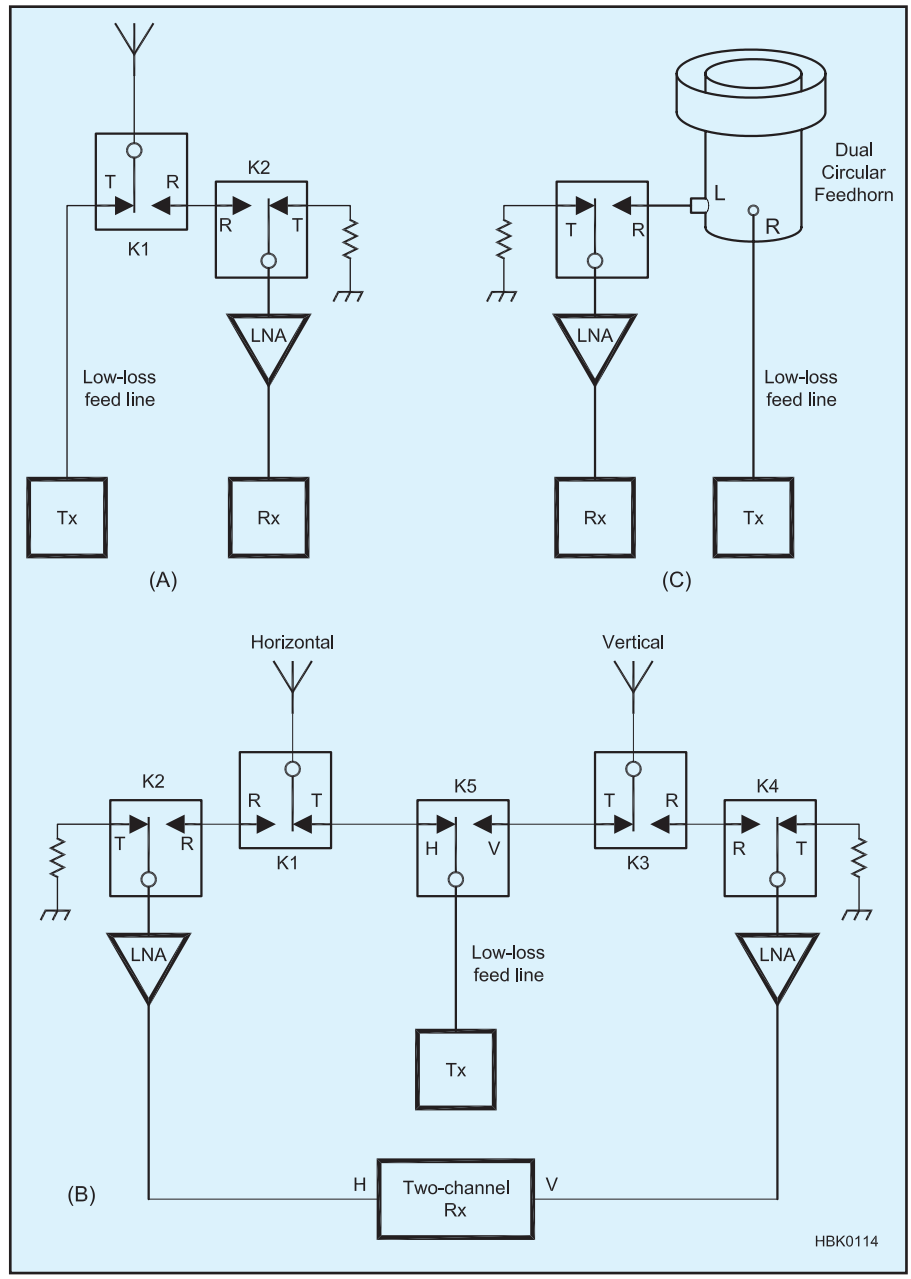


**Figure 76 — Recommended "front ends" for EME systems include low-noise preamplifiers (LNAs) mounted at the antenna and use separate feed lines for transmitting and receiving. Relay K2 shown in (A) may be omitted if K1 provides adequate isolation of the LNA while transmitting. An arrangement like that in (B) is recommended for a dual-polarization antenna such as an array of cross-Yagis. Transmitter power is sent to one polarization or the other, but received signals in both polarizations are amplified and sent on to a dual-channel receiver. Part (C) shows a suitable arrangement for circular polarization implemented with a two-port, dual-circular-polarization feed horn. In this case, no high-power TR relay is required.**

cant impact on system noise temperature. The feedhorn of a dish antenna can have a valuable high-pass effect that attenuates signals at lower frequencies.

The same antenna is generally used for both transmitting and receiving, so the LNA must be out of the line and protected when transmitting. **Figure 76A** illustrates a preferred switching arrangement that uses two separate feed lines: a low-loss line to carry transmitter power and a relatively inexpensive feed line from LNA to receiver. A high-power relay K1 at the antenna handles TR switching; a second relay, K2, may be used to protect the LNA in case the isolation at K1's receive port is inadequate.

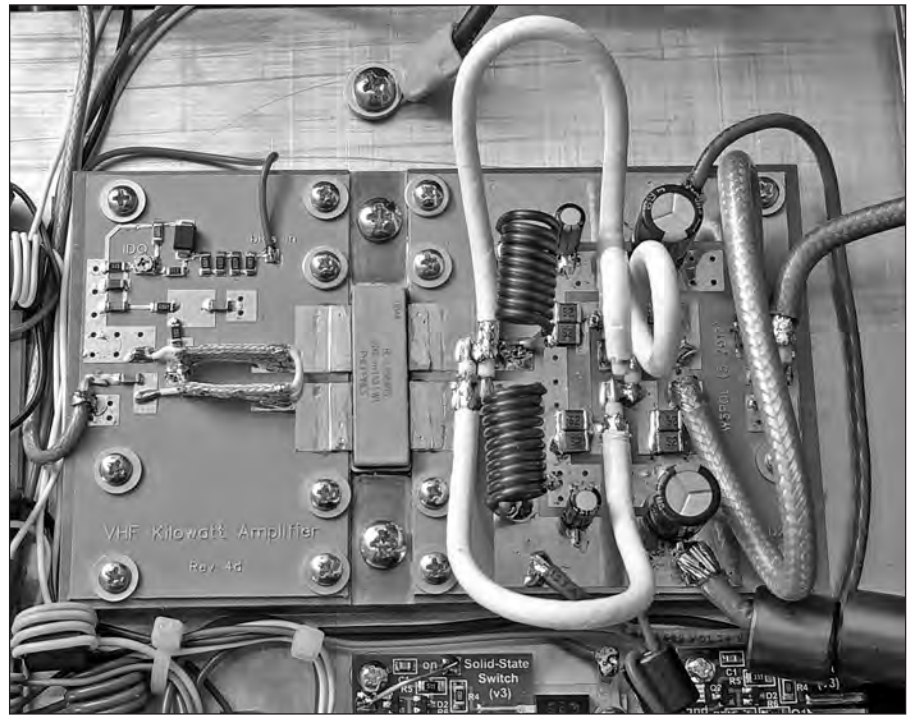
Additional relays are required in order to make best use of a dual-linear-polarization system. Figure 76B shows an arrangement that lets you select either horizontal or vertical polarization for transmitting (via relay K5) and use both polarizations simultaneously for receiving. A dual-channel receiver can form a linear combination of signals in the two channels to match the polarization of a desired signal exactly, whatever its angle. Such optimization is readily accomplished in a receiver whose last stages are defined and implemented in software, as in the highly effective *Linrad* system designed by SM5BSZ.[5] For digital EME using dual-polarization antennas, *Linrad* and a software program called *MAP65* make an especially powerful combination.[6]

With circular polarization you may not need a high-power TR relay at all. Figure 76C shows a typical arrangement with transmitter connected to one port of a feed horn providing both senses of circular polarization, and the LNA to the other port. Since the isolation between ports may be only 20 or 30 dB, a low-power relay protects the LNA during transmit periods. In all of these schemes, suitable sequencing should be used to assure that the LNA is disconnected before transmission can begin. Many amateurs find it best to use the energized position of TR relays on receive. When the station is not in use, preamplifiers will then be disconnected from the antenna.

## 11.3 Transmitters and Power Amplifiers

### FREQUENCY STABILITY

Weak signals are best detected in a bandwidth no wider than the signal itself. As a consequence, EME systems must use stable oscillators. For best results with CW your frequency drift over a minute or so should be no more than 10 Hz at the operating frequency; with digital modes the ideal target may be several times smaller. Most modern transceivers are stable enough at VHF, but some only marginally so at UHF.



The crystal oscillators used in transverters may need temperature compensation for adequate stability; better still, they can be phase-locked to an external high-stability reference oscillator. Many successful EME QSOs have been made on the microwave bands using 5-10 W transmitter power and parabolic dishes smaller than 2 m (up to 5.7 GHz) and even 1 m (at 10 and 24 GHz). These are significantly smaller systems than the baseline examples listed in Table 9. Such contacts generally depend on having stabilized local oscillators. Especially for digital EME, where detection bandwidths less than 10 Hz are used, unstable oscillators lead directly to loss of sensitivity.

### POWER OUTPUT

After frequency stability, the most important specification for an EME transmitter is power output. The maximum power practically achievable by amateurs ranges from 1500 W on the VHF and lower UHF bands down to the 100 W range at 10 GHz. Fortunately, the required power levels for EME

(A)

(B)

**Figure 77 —Solid-state power amplifier for 2 m built by W6PQL. (A) Outside cabinet view; (B) inside view showing the core of the amplifier.**

(Table 9) are compatible with these numbers. At 432 MHz and below, triode or tetrode vacuum tubes with external-anode construction can provide ample gain and power output. Some popular tubes include the 4CX250, 8930, 8874, 3CX800, 8877, GU-74B, GS-23B and GS-35B. Amplifiers using one or a pair of these (or other similar tubes) can provide output powers ranging up to 1000 or 1500 W on the 50 to 432 MHz bands. VHF and UHF power amplifiers based on solid state power devices have also become viable and attractive alternatives. Many amateurs have built solid-state power amplifiers (SSPAs) using these techniques, and commercial designs are available. **Figure 77** shows a kilowatt amplifier for 2 m made by W6PQL.[7]

At frequencies above 1 GHz, transit-time limitations and physical structures prevent most high-power vacuum tubes from performing well. For many years planar triodes in the 2C39/7289/3CX100 family were the mainstays of amateur 1296 MHz power amplifiers. These still work well, but today they are increasingly being replaced by SSPAs. As prices come down and power levels increase, these units are becoming more popular with EME operators. Surplus SSPAs usable on the 902, 2304 and 3456 MHz bands have been attractive buys in recent years, providing output power up to several hundred watts at reasonable cost. Two, four or even more units are sometimes used together to achieve higher output. SSPAs with at least 50 W output can be built and are available for the 5.7 and 10 GHz bands.

### RF SAFETY

One final point must be made in a discussion of high power amplifiers. Anyone who has thought about how a microwave oven works should know why RF safety is an important issue. Dangerous levels of radio frequency radiation exist inside and at short distances from power amplifiers and antennas. In normal operation, power density is highest in the immediate vicinity of small, low-gain antennas such as feeds for parabolic dishes. EME operators should be aware that ERP (effective radiated power) can be highly misleading as a guide to RF hazards. Somewhat counter-intuitively, a large, high-gain antenna helps to reduce local RF hazards by distributing RF power over a large physical area, thus reducing power density. Be sure to read the RF Safety section in the **Safe Practices** chapter and pay attention to the RF protection guidelines there.

# 12 Getting Started with EME

Perhaps you already have a weak-signal VHF or UHF station with somewhat lesser capabilities than those recommended in Tables 8 and 9, and would like to make a few EME contacts before possibly undertaking the task of assembling a "real" EME station. On 144 and 432 MHz — probably the easiest EME bands on which to get started — you can visually point your single long Yagi at the rising or setting moon and work some of the larger EME stations. Your daily newspaper probably lists the approximate times of moon rise and moon set in your vicinity; many simple web- or smartphone-based calculators can give you that information as well as the Moon's azimuth and elevation at any particular time (see the sidebar, "Computer and Internet Resources for EME").

These aids may be all you need to make your first EME contacts, especially if you take advantage of the weak-signal capabilities of an efficient digital mode. To optimize your chances of success, adapt your operating procedures to the prevailing standards that other EME operators will be using, as discussed below. For your first attempts you may want to make prearranged schedules with some established stations.

## 12.1 Tracking the Moon

For serious EME work you'll want a more general way of keeping your antenna pointed at the Moon. The Earth and Moon complete their mutual orbit every 27.3 days, one sidereal month. The lunar orbit is inclined to the plane of the ecliptic, the Earth-Sun orbital plane, by 5.1°. Since the Earth's equator is itself inclined at 23.5° to the ecliptic, the Moon's path through the sky swings north and south of the equator by as much as 28° in a monthly cycle (see Figure 63).

Predicting the Moon's exact position is a complicated problem in celestial mechanics, but is readily handled to sufficient accuracy by simple computer software. In general the problem can be reduced to 1) calculating the Moon's position on the sky, as seen by a hypothetical observer at the center of the Earth; 2) applying a parallax correction to yield the lunar position at a specified location on the Earth's surface; and 3) converting the astronomical coordinates of right ascension and declination to azimuth and elevation at the specified terrestrial location.

Of course, the Earth's rotation and Moon's orbital motion imply that the Moon's direction is constantly changing. Suitable computer software can follow these changes and generate the necessary commands to keep your antenna pointed at the Moon. Several free or inexpensive software packages with moon-tracking features are listed in the sidebar, "Computer and Internet Resources for EME," and such facilities are built into the programs *WSJT-X* and *MAP65* widely used for digital EME. For good results you should aim for pointing accuracies of ¼ of your half-power beamwidth or better.

## 12.2 System Evaluation

Careful measurements of your EME system's performance can help to determine where station improvements can be made. Transmitter performance is essentially determined by power output, feed line losses and antenna gain. The first two can be measured in standard ways, but antenna gain is much more difficult. The most useful figure of merit for receiving performance is $G/T_s$, and while absolute measurements of either G or $T_s$ separately are difficult, you can measure their ratio with useful accuracy and compare it with expectations. One technique particularly useful at 432 MHz and above is to use the sun as a broadband noise source. Point your antenna at cold sky and then at the sun, and measure y, the ratio of received noise power in the two directions. Operate your receiver at maximum bandwidth with the AGC off, and if possible make the observations with the sun at elevation 30° or higher.

To calculate $G/T_s$ from y, you will need a contemporaneous estimate of solar flux density at your operating frequency. Daily measurements of solar flux are obtained at a number of standard frequencies and made available online (see the sidebar, "Computer and Internet Resources for EME"); you can interpolate an approximate flux value for the amateur band in question. Solar flux densities vary with sunspot activity, and day-to-day or even hour-to-hour variations are especially large at lower frequencies and near solar maximum. Representative monthly median

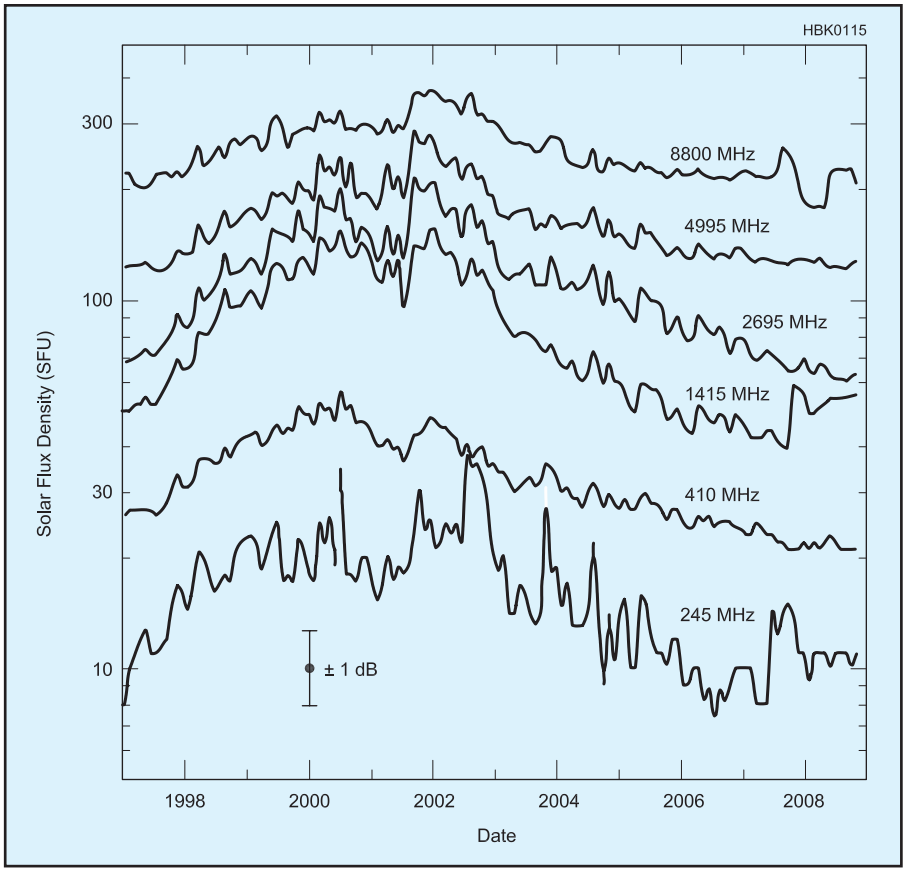


**Figure 78 — Monthly median values of solar flux density at six frequencies, over the 11 years of solar cycle 23. Original data are from the Sagamore Hill Observatory in Massachusetts. At the lower frequencies, and especially near solar maximum, day-to-day and even hour-to-hour upward variations can be an order of magnitude larger than those in the monthly medians.**

values for six frequencies are presented in **Figure 78** over sunspot cycle 23. As a starting point, you can estimate a value of solar flux for your band and a similar point in the current sunspot cycle directly from Figure 78. Then, if $S^*$ is the solar flux density in units of W $m^{-2}$ $Hz^{-1}$ and y is expressed as a dimensionless ratio, the corresponding value of $G/T_s$ in dB is given by

$$\frac{G}{(T_s)} = 10 \log \left( \frac{8\pi k (y-1)}{S^* \lambda^2} \right)$$

Solar flux is usually quoted in Solar Flux Units (1 SFU = $10^{-22}$ W $m^{-2}$ $Hz^{-1}$), and with S in those units Equation (12) can be reduced to the simpler relation

$$\frac{G}{(T_s)} = 10 \log \left( \frac{3.47\ (y-1)}{S \lambda^2} \right)$$

Representative values of $G/T_s$ and $Y_{sun}$ = 10 log y for the example antennas of Table 9 are given in columns 4 and 5 of **Table 10**. The tabulated values of $Y_{sun}$ are based on quiet-sun flux densities typical of years near sunspot minimum.

Of course, receiving your own echoes from the Moon provides the best guarantee that your equipment is capable of EME communication with comparable stations. Transmitting a few dashes, then standing by to hear your lunar echo some 2.5 s later, brings a thrill that most hams never forget. With suitable signal-processing software, echoes can be detected and measured even with relatively low-power equipment. Program *WSJT-X* (see the sidebar, "Computer and Internet Resources for EME") includes an automated echo-testing facility that is useful for quantitative measurements even if your echoes are many dB below the audible threshold.

## 12.3 Operating Procedures

The more that's known about likely structure, content and timing of a transmitted message, the easier it is to copy. EME signals are often near the threshold of readability, so it is highly desirable to standardize operating procedures and message structure, and to provide transmissions with enough redundancy to capitalize on signal peaks and bridge likely gaps in reception.

You may wish to make your first EME QSOs with the aid of explicit schedules: that is, arrangements to attempt a contact with a particular station at a specified time and frequency. EME schedules usually state the duration of timed transmissions as well as starting time, transmitter frequency, and an indication of which station will transmit first. For a minimal QSO, message information is often reduced to the bare essentials of call signs, signal reports and acknowledgments. The signal report is sometimes reduced to a "yes or no" indication of whether both call signs have been successfully copied.

Remember to allow for Doppler shifts, especially at higher frequencies where the offset may exceed your received bandwidth. Most moon-tracking software used for EME can display the expected frequency shift for your own echoes as well as that for a distant station. In a scheduled QSO attempt, keep your transceiver set to the schedule frequency and use its RIT control to search for the other station around his expected Doppler shift. When looking for contacts at random, especially at 432 MHz and above, set your RIT to the expected Doppler shift of your own echoes. If a station you copy does likewise, you will find each other's signals on the same frequency as your own echoes. Many operators also benefit from using a software-driven panoramic spectral display of the "waterfall" variety, which can make signal acquisition much easier. The program *WSJT-X*, widely used for digital EME, can be configured to compensate for EME Doppler shifts automatically with most transceivers.

### CW EME FORMAT

By convention, a minimal CW EME contact usually follows a format something like the sequence of messages in **Table 11**. If timed TR sequences are being used, the essential

**Table 10**

**Representative $G/T_s$ and $Y_{sun}$ for Example Antennas**

| *Freq (MHz)* | *Ant Type*[1] | *G (dBi)* | *$G/T_s$ (dB)* | *$Y_{sun}$ (dB)* |
|---|---|---|---|---|
| 144 | 4×6 m | 21.0 | –3.8 | 4 |
| 432 | 4×6 m | 25.0 | 5.8 | 12 |
| 1296 | 3 m | 29.5 | 11.1 | 11 |
| 2304 | 3 m | 34.5 | 15.6 | 11 |
| 3456 | 2 m | 34.8 | 15.3 | 9 |
| 5760 | 2 m | 39.2 | 18.8 | 9 |
| 10368 | 2 m | 44.3 | 22.4 | 11 |

[1]Example antennas for 144 and 432 MHz are Yagi arrays with stated lengths; those for 1296 MHz and higher are parabolic dishes of specified diameter.

**Typical Messages in a Minimal EME CW Contact**

| *Period* | *Message* |
|---|---|
| 1 | CQ CQ CQ DE W6XYZ W6XYZ … |
| 2 | W6XYZ DE K1ABC K1ABC … |
| 3 | K1ABC DE W6XYZ OOO OOO … |
| 4 | W6XYZ DE K1ABC RO RO RO … |
| 5 | K1ABC DE W6XYZ RRR RRR … |
| 6 | W6XYZ DE K1ABC TNX 73 … |

information is repeated for the full duration of a sequence.

The standard QSO procedures involve a number of different messages sent in sequence, and operators do not proceed to the next message until they have copied the essential information (call signs, signal report, acknowledgements) in previous messages. After call signs have been copied, a signal report is sent. Because CW dahs are easier to discern than dits, a default EME signal report (essentially meaning "I have copied both call signs") is the letter O. A station receiving call signs and O responds with RO, and a final acknowledgment of a valid contact is signified by sending RRR …. On 432 MHz and above, the letter M is sometimes used as an alternative signal report meaning "both call signs copied with difficulty." Of course, when signals are adequate for reasonably good copy normal RST signal reports can be used and other restrictions on message structure and timing relaxed.

In non-scheduled operation, it frequently happens (for example, in response to your CQ) that you can recognize and copy your own call more easily than the other station's call. The sequence YYY… (for "*Y*our call") can be sent to ask a calling station to send his call only, repeating it many times. A contact is considered complete and valid when RRR has been received (after message number 5 in Table 11 has been received). However, at this point the other station does not know that his acknowledgment was copied, so it is normal to finish with something like message 6.

The conventional duration of transmit and receive periods is different on different bands and has evolved somewhat over time. On 50 and 144 MHz, stations usually transmit for one full minute and then receive for a full minute. On 432 MHz and above, schedules with 2.5-minute transmissions have been standard. The longer period gives stations with mechanically variable polarization adequate time to peak a received signal.

CW sending speed is generally around 12 to 15 WPM. Some operators find it helpful to use greater-than-normal spacing between complete letters. Keep in mind that characters sent too slowly may be chopped up by typical EME fading, while code sent too fast will be jumbled. When transmitting call sequences, send the other station's call once, followed by "DE" and your own call once or twice. Then pause and repeat the sequence. This cadence sets a rhythm so that the receiving operator can anticipate when the missing parts of a message can be expected to arrive. Send with proper spacing; the use of a programmable keyer or computer keyboard-to-Morse program is especially helpful and encouraged. A signal buried in the noise and accompanied by fading is hard enough to copy, without the added complication of irregular sending.

### DIGITAL EME

Since 2003 most digital EME has been done using the JT65 protocol as implemented in computer programs *WSJT*, *MAP65* and most recently *WSJT-X* (see the sidebar, "Computer and Internet Resources for EME"). Like other popular digital modes, JT65 requires a personal computer with a sound card for audio input and output. It uses structured message formats, a Reed Solomon error-correcting code with slightly more than five-fold redundancy and 1-minute TR sequences. Signal peaks and dropouts due to multipath fading do not affect individual characters or words, but rather the probability of decoding the whole message. The modulation is 65-tone frequency shift keying (65-FSK) with computer-generated audio tones modulating a single-sideband transmitter in USB mode.

As expected from theory, results show that JT65 contacts can be made at signal levels more than 10 dB below those needed for CW. The detection bandwidth implemented in receiving software for JT65 is as small as

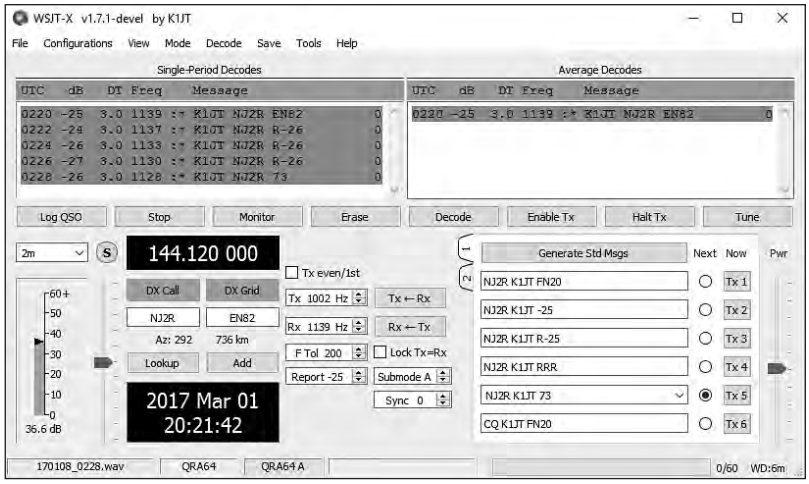

**Figure 79 — Screen shot of computer program *WSJT-X* showing an EME QSO on 2m between K1JT and NJ2R, using the QRA64 protocol.**

**Table 12**
**Typical Messages in a JT65 EME Contact**

| *Period* | *Using Shorthand Messages* | *Using Long-Form Messages* |
|---|---|---|
| 1 | CQ W6XYZ CN87 | CQ W6XYZ CN87 |
| 2 | W6XYZ K1ABC FN42 | W6XYZ K1ABC FN42 |
| 3 | K1ABC W6XYZ CN87 OOO | K1ABC W6XYZ –21 |
| 4 | RO | W6XYZ K1ABC R–19 |
| 5 | RRR | K1ABC W6XYZ RRR |
| 6 | 73 | TNX RAY 73 GL |

2.7 Hz. This may be compared with minimum bandwidths of order 50 Hz for 15 WPM CW.

The JT4 and QRA64 protocols use the same structured message formats and operating procedures as JT65. JT4 uses a convolutional error-correcting code and 4-FSK modulation. Submodes offer increasingly wide tone separations that can be especially helpful on paths with large Doppler spread. For example, JT4F (tone separation 157.5 Hz) is widely used for EME on 10 and 24 GHz. QRA64 is a recent new addition in *WSJT-X*. It uses a *Q-ary Repeat-Accumulate* code — a type of non-binary low-density parity-check code currently at the forefront of research in communication theory. As implemented in *WSJT-X*, submode QRA64A had been shown to be very effective for EME on 144 MHz, and QRA64D had become the preferred mode for EME at 10 GHz.

Basic procedures for minimal contacts with any of these digital modes are similar to those for CW. Examples of typical message sequences are shown in **Table 12**. Standard messages include space reserved for Maidenhead grid locators, so this information is normally exchanged along with call signs. Following CW practice, you should proceed to the next message in the QSO sequence only when information from the previous step has been copied. In JT4 and JT65 a default signal report may be sent as OOO, but many operators prefer to send and receive numerical signal reports (giving the signal strength in dB, relative to noise power in a standard 2500 Hz bandwidth) as measured by the receiving software. Messages using such reports are shown in the final column of Table 12. Many additional details on the usage of the digital protocols can be found in documentation distributed with the *WSJT-X* program. **Figure 79** shows an example screen shot with the messages exchanged in a QSO between NJ2R and K1JT via 144 MHz EME.

## 12.4 Finding QSO Partners

At the time of this writing (early 2017) levels of EME activity are highest on 144 MHz. Almost any time the Moon is above your horizon (excluding a few days each month when it is near the plane of the Milky Way), you can find JT65 EME signals in the frequency range 144.100 to 144.160 MHz — often dozens of them, especially on weekends. Hundreds of operators, worldwide, are "on the Moon" regularly using JT65 (and increasingly also QRA64) on 144 MHz. Some of the larger stations have made EME contacts with more than 2000 other stations. Operating frequencies of particular stations are often posted on real-time loggers and on the website *LiveCQ* (see the sidebar, "Computer and Internet Resources for EME"). Explicit schedules can also be made on the loggers, and this is a good way to initiate your first EME contacts. Don't compromise a true EME contact by communicating via the logger after a QSO attempt has been started, however.

CW activity on the 144 MHz band, as well as EME activity on higher bands in any mode, tends to be concentrated in activity weekends scheduled once each month when the Moon is in a favorable location. After 144 MHz, the bands with most EME activity are 1296 and 432 MHz. On those bands random CW (and occasionally SSB) activity is mostly found between 5 and 30 kHz above the nominal sub-band boundary (for example, between 1296.005 and 1296.030), and digital activity is between .060 and .090, concentrating around .065 or .070. A hundred or more stations are typically active on these bands during the annual ARRL International EME Competition and in other major operating events.

The higher microwave bands 2.3 through 10 GHz have at least several dozen regularly active stations. On these and higher bands activity tends to concentrate around .100. Keep in mind that different band segments may be assigned in different parts of the world.[8] For example, North American stations use 2304.100, but some Europeans work around 2320.100. EME activity on the 50, 222 and 902 MHz bands is mostly done with prearranged schedules. The sidebar, "Computer and Internet Resources for EME" lists some resources that can help you to find schedule partners and the dates of EME contests and activity weekends.

# 14 Glossary of Space Communications Terminology

***AMSAT*** — A registered trademark of the Radio Amateur Satellite Corporation, a nonprofit scientific/educational organization located in Washington, DC. It builds and operates Amateur Radio satellites and has sponsored the OSCAR program since the launch of OSCAR 5. (AMSAT, 10605 Concord St, #304, Kensington, MD 20895; **www.amsat.org**)

***Anomalistic period*** — The elapsed time between two successive perigees of a satellite.

***Antenna temperature*** — Used in EME system evaluation, a measure of the noise picked up by the antenna from all noise sources in the field of view, weighted by the antenna pattern.

***AO-#*** — The designator used for AMSAT OSCAR spacecraft in flight, by sequence number.

***AOS*** — Acquisition of signal. The time at which radio signals are first heard from a satellite, usually just after it rises above the horizon.

***Apogee*** — The point in a satellite's orbit where it is farthest from Earth.

***Argument of perigee*** — The polar angle that locates the perigee point of a satellite in the orbital plane; drawn between the ascending node, geocenter, and perigee; and measured from the ascending node in the direction of satellite motion.

***Ascending node*** — The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Southern Hemisphere into the Northern Hemisphere.

***Az-el mount*** — An antenna mount that allows antenna positioning in both the azimuth and elevation planes.

***Azimuth*** — Direction (side-to-side in the horizontal plane) from a given point on Earth, usually expressed in degrees. North = 0° or 360°; East = 90°; South = 180°; West = 270°.

***Circular polarization (CP)*** —Describes an electromagnetic wave in which the electric and magnetic fields are rotating. If the electric field vector is rotating in a clockwise sense, then it is called right-hand circular polarization and if the electric field is rotating in a counterclockwise sense, it is called left-hand circular polarization. Polarization sense is determined looking in the direction in which the wave is traveling.

***Cross-polarized*** — Antennas that are aligned with their polarization at right angles or accept opposite senses of circular polarization.

***Descending node*** — The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Northern Hemisphere into the Southern Hemisphere.

***Desense*** — A problem characteristic of many radio receivers in which a strong RF signal overloads the receiver, reducing sensitivity.

***Doppler effect*** — An apparent shift in frequency caused by a change in distance between transmitter and receiver.

***Downlink*** — The frequency on which radio signals originate from a satellite for reception by stations on Earth.

***Earth station*** — A radio station, on or near the surface of the Earth, designed to transmit or receive to/from a spacecraft.

***Eccentricity*** — The orbital parameter used to describe the geometric shape of an elliptical orbit; eccentricity values vary from e = 0 to e = 1, where e = 0 describes a circle and e approaches 1 for a very long, thin ellipse.

***EIRP*** — Effective isotropic radiated power. Same as ERP except the antenna reference is an isotropic radiator.

***Elevation*** — Angle above the local horizontal plane, usually specified in degrees. (0° = plane tangent to the Earth's surface at your location; 90° = straight up, perpendicular to the plane of the Earth).

***EME*** — Earth-Moon-Earth (see also ***Moonbounce***)

***Epoch*** — The reference time at which a particular set of parameters describing satellite motion (*Keplerian elements*) are defined.

***EQX*** — The reference equator crossing of the ascending node of a satellite orbit, usually specified in UTC and degrees of longitude of the crossing.

***ERP*** — Effective radiated power. System power output after transmission-line losses and antenna gain (referenced to a dipole) are considered.

***ESA*** — European Space Agency. A consortium of European governmental groups pooling resources for space exploration and development.

***Faraday rotation*** — A rotation of the polarization of radio waves when the waves travel through the ionosphere, in the presence of the Earth's magnetic field.

***FO-#*** — The designator used for Japanese amateur satellites, by sequence number. Fuji-OSCAR 12 and Fuji-OSCAR 20 were the first two such spacecraft.

***Geocenter*** — The center of the Earth.

***Geostationary orbit*** — A satellite orbit at such an altitude (approximately 22,300 miles) over the equator that the satellite appears to be fixed above a given point.

***Ground gain*** — Reflections from the ground in front of an antenna can add as much as 6 dB to the effective gain at certain elevation angles.

***Groundtrack*** — The imaginary line traced on the surface of the Earth by the subsatellite point (SSP).

***Inclination*** — The angle between the orbital plane of a satellite and the equatorial plane of the Earth.

***Increment*** — The change in longitude of ascending node between two successive passes of a specified satellite, measured in degrees West per orbit.

***Iskra*** — Soviet low-orbit satellites launched manually by cosmonauts aboard Salyut missions. Iskra means "spark" in Russian.

***JT65*** — A digital mode used for EME communications.

***Keplerian Elements*** — The classical set of six orbital element numbers used to define and compute satellite orbital motions. The set is comprised of inclination, Right Ascension of Ascending Node (RAAN), eccentricity, argument of perigee, mean anomaly and mean motion, all specified at a particular epoch or reference year, day and time. Additionally, a decay rate or drag factor is usually included to refine the computation.

***LEO*** — Low Earth Orbit satellite such as the Phase 1 and Phase 2 OSCARs.

***LHCP*** — Left-hand circular polarization.

***Libration fading*** — Rapid fading of EME signals caused by changing relative geometry of reflecting features on the Moon's surface and an observer on Earth.

***LNA*** — Low noise amplifier — a preamplifier mounted as close to the antenna terminals as possible for satellite and EME communication.

***LOS*** — Loss of signal — The time when a satellite passes out of range and signals from it can no longer be heard. This usually occurs just after the satellite goes below the horizon.

***Mean anomaly (MA)*** — An angle that increases uniformly with time, starting at perigee, used to indicate where a satellite is located along its orbit. MA is usually specified at the reference epoch time where the Keplerian elements are defined. For AO-10 the orbital time is divided into 256 parts, rather than degrees of a circle, and MA (sometimes called phase) is specified from 0 to 255. Perigee is therefore at MA = 0 with apogee at MA = 128.

***Mean motion*** — The Keplerian element to indicate the complete number of orbits a satellite makes in a day.

***Microsat*** — Collective name given to a series of small amateur satellites having store-and-forward capability (OSCARs 14-19, for example).

***Molniya*** — Type of elliptical orbit, first used in the Russian Molniya series, that features a ground track that more or less repeats on a daily basis.

***Moonbounce*** — A common name for EME communication in which signals are bounced off the Moon before being received.

***NASA*** — National Aeronautics and Space Administration, the US space agency.

***Nodal period*** — The amount of time between two successive ascending nodes of satellite orbit.

***Orbital elements*** — See ***Keplerian Elements***.

***Orbital plane*** — An imaginary plane, extending throughout space, that contains the satellite orbit.

***OSCAR*** — Orbiting Satellite Carrying Amateur Radio.

***PACSAT*** — Packet radio satellite (see ***Microsat*** and ***UoSAT-OSCAR***).

***Parabolic (dish) antenna*** — An antenna reflector that is a portion of a paraboloid of revolution. Used mainly at UHF and higher frequencies to obtain high gain and narrow beamwidth when excited by one of a variety of driven elements placed at the dish focus to illuminate the reflector.

***Pass*** — An orbit of a satellite.

***Passband*** — The range of frequencies handled by a satellite translator or transponder.

***Path loss*** — The total signal loss between transmitting and receiving stations relative to the total radiated signal energy.

***Perigee*** — The point in a satellite's orbit where it is closest to Earth.

***Period*** — The time required for a satellite to make one complete revolution about the Earth. See ***Anomalistic period*** and ***Nodal period***.

***Phase I*** — The term given to the earliest, short-lived, low Earth orbit (LEO) OSCAR satellites that were not equipped with solar cells. When their batteries were depleted, they ceased operating.

***Phase 2*** — LEO OSCAR satellites. Equipped with solar panels that powered the spacecraft systems and recharged their batteries, these satellites have been shown to be capable of lasting up to five years (OSCARs 6, 7 and 8, for example).

***Phase 3*** — Extended-range, high-elliptical-orbit OSCAR satellites with very long-lived solar power systems (OSCARs 10 and 40, for example).

***Phase 4*** — Proposed OSCAR satellites in geostationary orbits.

***Polar Orbit*** — A low, circular orbit inclined so that it passes over the Earth's poles.

***Precession*** — An effect that is characteristic of AO-10 and AO-40 orbits. The satellite apogee SSP will gradually change over time.

***Project OSCAR*** — The California-based group, among the first to recognize the potential of space for Amateur Radio; responsible for OSCARs I through IV.

***QRP days*** — Special orbits set aside for very low power uplink operating through the satellites.

***RAAN*** — Right Ascension of Ascending Node. The Keplerian element specifying the angular distance, measured eastward along the celestial equator, between the vernal equinox and the hour circle of the ascending node of a spacecraft. This can be simplified to mean roughly the longitude of the ascending node.

***Radio Sputnik*** — Russian Amateur Radio satellites (see ***RS #***).

***Reference orbit*** — The orbit of Phase II satellites beginning with the first ascending node during that UTC day.

***RHCP*** — Right-hand circular polarization.

***RS #*** — The designator used for most Russian Amateur Radio satellites (RS-1 through RS-15, for example).

***Satellite pass*** — Segment of orbit during which the satellite "passes" nearby and in range of a particular ground station.

***Sidereal day*** — The amount of time required for the Earth to rotate exactly 360° about its axis with respect to the "fixed" stars. The sidereal day contains 1436.07 minutes (see ***Solar day***).

***Sidereal month*** — The Earth and Moon complete their mutual orbit (with respect to fixed stars) every 27.3 days, one sidereal month.

***Solar day*** — The solar day, by definition, contains exactly 24 hours (1440 minutes). During the solar day the Earth rotates slightly more than 360° about its axis with respect to "fixed" stars (see ***Sidereal day***).

***Spin modulation*** — Periodic amplitude fade-and-peak resulting from the rotation of a satellite's antennas about its spin axis, rotating the antenna peaks and nulls.

***SSP*** — Subsatellite point. Point on the surface of the Earth directly between the satellite and the geocenter.

***System noise temperature*** — Used in EME system evaluation, a measure of noise picked up by the antenna plus noise generated in the receiver.

***Telemetry*** — Radio signals, originating at a satellite, that convey information on the performance or status of onboard subsystems. Also refers to the information itself.

***Transponder*** — A device onboard a satellite that receives radio signals in one segment of the spectrum, amplifies them, translates (shifts) their frequency to another segment of the spectrum and retransmits them. Also called linear translator.

***UoSAT-OSCAR (UO #)*** — Amateur Radio satellites built under the coordination of radio amateurs and educators at the University of Surrey, England.

***Uplink*** — The frequency at which signals are transmitted from ground stations to a satellite.

***Visibility Circle*** — The range of area on the Earth that are "seen" by a satellite. This is also called the "footprint" for that satellite.

***Window*** — Overlap region between acquisition circles of two ground stations referenced to a specific satellite. Communication between two stations is possible when the subsatellite point is within the window.

***WSJT-X*** — A suite of computer software that includes tools for EME communication.

# Digital Communications

In this operating supplement to the *ARRL Handbook*, updated in early 2021, Steve Ford, WB8IMY, discusses the techniques involved in assembling and configuring station components for operating on the various HF and VHF digital modes. Today's digital communication choices range from keyboard-based modes such as classic RTTY, packet radio, and PSK31, to FT8, FT4, JT65, digital voice, local high-speed multimedia networks and VHF/UHF networks linked by the internet. Related information may be found in the **Modulation** and **Digital Protocols and Modes** chapters. Unless otherwise noted, references to other chapters refer to chapters in the print version of the *ARRL Handbook*.

Amateur digital communication is today a mainstream activity, having far outgrown its history as a niche activity. From the end of World War II until the early 1980s, *radioteletype*, better known as *RTTY*, was *the* amateur radio digital mode. If you had visited an amateur RTTY station prior to about 1977, you probably would have seen a mechanical teletype machine, complete with rolls of yellow paper. The teletype may have been connected to the transceiver through an interface known as a *TU*, or *terminal unit*. An oscilloscope would probably have graced the layout as well, used for proper tuning of the received signal.

When affordable microprocessor technology appeared in the late 1970s, terminal units evolved as well. Some included self-contained keyboards and video displays, making the mechanical teletype obsolete. As personal computers evolved, they became perfect companions for TUs. In this configuration, the PC functioned as a "dumb terminal," displaying the received data *from* the TU and sending data *to* the TU for transmission. TUs of this era offered ultra-sharp receive filters that allowed hams to copy weak signals amid interference.

In the late 1980s, conventional terminal units began to yield to sophisticated microprocessor devices known as *multimode controllers*. As the name suggests, these compact units handle several different digital modes in one package, typically RTTY, packet, AMTOR and PACTOR. Like TUs, multimode controllers are stand-alone devices that communicate with a personal computer acting as a dumb terminal. All the heavy lifting is being done by the controller and its self-contained software known as *firmware*.

In the early 1990s, sound cards appeared for personal computers. As sound cards became more powerful, hams began to realize their potential. With the right software, a sound card could take received audio directly from the radio and translate it into digital information. The same sound card could also create various forms of digital audio modulation for transmission. The first "sound card mode" was PSK31, developed by Peter Martinez, G3PLX. In the years that followed, sound cards became more powerful and versatile. Hams responded by developing new digital modes to take advantage of the advances.

Hardware controllers are still with us, but they are primarily used for modes like packet and PACTOR that require more processing muscle and precision timing than a typical personal computer can provide on its own. Other amateur digital modes such as D-STAR depend on specially designed transceivers that combine the radio hardware with dedicated digital processing firmware.

## 1 Sound Device Modes

Sound device technology dominates the amateur HF digital communications world. Although the term *sound card* is commonly used, the techniques discussed in this section apply to motherboard-embedded sound chip sets, which are extremely common in computer systems today, and to external sound processing devices, including those found in a number of modern transceivers. We'll use the term "sound device" to refer to any of these hardware implementations.

The sound device modes in use today include FT8, FT4, PSK, RTTY, MFSK16, Olivia, JT65, Hellschreiber, MSK144, WSPR, and many more. There are also sound-device applications for digital voice, discussed later in this supplement, and for slow-scan TV, discussed in the **Image Communications** supplement.

As this was written in 2021, FT8 had become the most popular HF digital communication mode, both for casual contacts and for DXing. The popularity of FT8 notwithstanding, radioteletype (RTTY) remains the chief HF mode for contesting, although FT8 is making serious inroads in this application as well. In fact, a relatively new "cousin" of FT8, known as FT4, is specifically designed for contesting.

All other HF digital modes play minor roles, but each has characteristics that provide benefits depending on the use case. Olivia and MFSK16, for example, provide more robust copy under poor conditions. WSPR is the most popular mode for propagation testing. On VHF and above, the *WSJT-X* software suite offers modes specifically designed for meteor scatter and moonbounce work. *WSJT-X* is free and available for Windows, Linux, and macOS at **physics.princeton.edu/pulsar/k1jt/wsjtx.html**.

Regardless of the mode in question, the sound device functions as the critical link. It is put to work as a digital-to-analog (D/A) and analog-to-digital (A/D) converter. In its A/D role, the sound device takes receiver audio and converts it to digital information. During transmission, the sound device is used as a D/A converter, taking digital information from the software application and creating a corresponding analog signal that is fed to the transceiver. (For more information on A/D and D/A converters, see the **DSP and SDR Fundamentals** chapter of this *Handbook*.)

## 1.1 The Evolution of Sound Devices

In the early days of amateur radio sound device modes, the computer sound card (or motherboard sound chipset) was *the* critical component in every amateur station. But for most amateur applications today, the sound device has moved out of the computer and into external interfaces, or even into transceivers themselves. See **Figure 1**. Rather than traditional interfaces that merely passed analog audio signals between radios and computers, modern interfaces contain their own A/D and D/A devices. The connection to the computer is strictly for the transfer of digital information, typically through a USB cable.

Transceivers are increasingly taking the next step by bringing the A/D and D/A conversion process into the radio. There is no external interface whatsoever; the radio connects directly to the computer. We can expect to see an increasingly number of transceivers taking this approach.

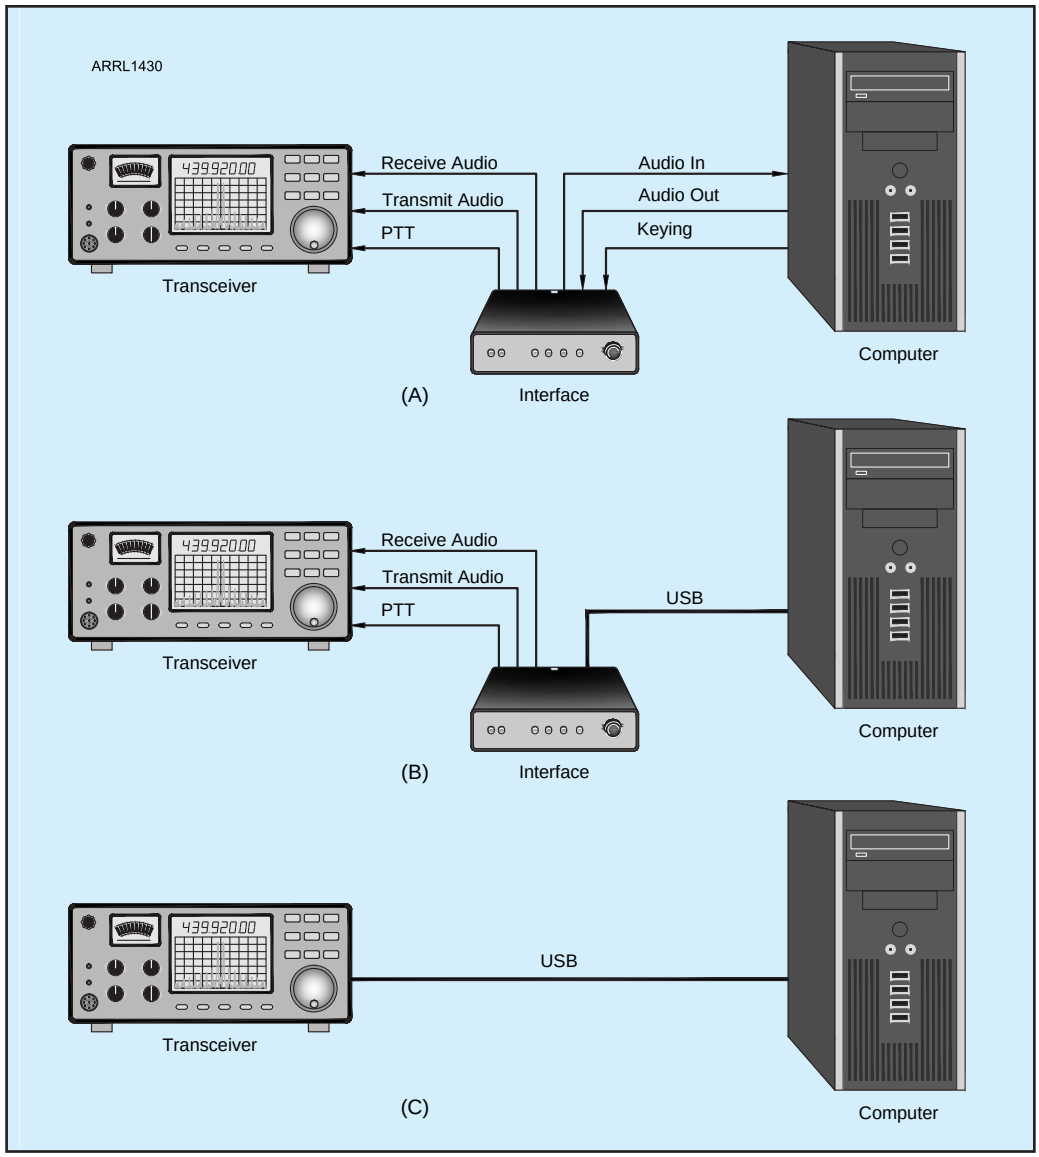

**Figure 1 — Three of the most common configurations for interfacing your transceiver with your computer. (A) The most common setup for many years was based on an interface that took transmit and receive audio from the computer sound card, along with transmit/receive keying from one of the computer's COM ports, and passed everything to the transceiver in a way that kept the signal lines isolated. This type of interface is increasingly uncommon. (B) Many interfaces available at the time this was written are USB devices. A single USB cable plugs into the computer. Not only is the computer sound card not used, the interface contains its own sound device. In turn, the interface supplies transmit audio to the radio, processes receive audio from the radio and handles transmit/receive keying. (C) The future will likely see the disappearance of the interface entirely as transceivers incorporate their own computer interfacing. Today, several moderate to higher-priced rigs have added this feature.**

### AFSK AND FSK

Most sound device modes rely on some form of frequency and/or phase-shift keying to create digitally modulated RF signals. This modulation takes place at audio frequencies with the sound device audio output applied directly to an SSB voice transceiver, either at the microphone jack or at a rear-panel accessory jack, and is called *audio frequency shift keying* (*AFSK*).

RTTY, PACTOR I and AMTOR signals can be sent using AFSK, and often are. It is also possible to transmit these modes by applying discrete binary data *directly* to the transceiver. This technique is known simply as direct *frequency-shift keying (FSK)*.

For example, each character in the Baudot RTTY

code is composed of five bits. When modulated with AFSK, a "1" bit is usually represented by a 2125-Hz tone and is known as a *mark*. A "0" bit is represented by a 2295-Hz tone called a *space*. The difference between the mark and space is 170 Hz, called the *shift*. When applied to a single-sideband transceiver, this AFSK audio signal effectively generates an RF output signal that shifts back and forth between the mark and space frequencies.

A transceiver that supports FSK, however, can accept mark/space digital data directly from the computer and will use that information to automatically generate the frequency-shifting RF output. No audio signal is applied to the transceiver when operating FSK.

Is there an advantage to using AFSK or FSK? In years past, transceivers that did not support FSK operation often did not allow the use of narrow IF filtering. Narrow filters were reserved for CW, not the SSB voice mode used with AFSK. If you wanted to use RTTY with such a rig, you had to use AFSK and contend with the wider (2.4 kHz or so) SSB IF bandwidth, or else add an external audio filter. FSK-capable transceivers, on the other hand, allowed the RTTY operator to select narrow filters, reducing receive interference in crowded bands.

Many of today's transceivers offer adjustable-bandwidth digital signal processing (DSP) filters in the IF stages that can be used with any operating mode. This has effectively eliminated the FSK advantage, at least for receiving.

The appeal of FSK remains, however, when it comes to transmitting. A *properly modulated* AFSK signal is indistinguishable from FSK, but it is relatively easy to overdrive an SSB transmitter when applying an audio signal from a sound device (more on this in the next section). With FSK this is never an issue. You simply feed data from the computer to the radio; the radio does the rest.

This is why many RTTY operators still use FSK, and it's why transceiver manufacturers still offer FSK modes (sometimes labeled **DATA** or **RTTY**) in their products. Several sound device interfaces support FSK by providing a dedicated TTL circuit between the computer COM port, where the FSK data appears, and the transceiver FSK input. When used in this fashion, the sound device does not generate a transmit audio signal at its output. Instead, the RTTY software keys the various lines at the COM port to send the FSK data.

If the interface you've chosen doesn't support FSK, you can build your own TTL interface using the circuit shown in **Figure 2**. This simple circuit uses a transistor that is keyed on and off by data pulses appearing on the COM port TxD pin (pin 3 on a 9-pin COM port). New computers may not have a serial COM port. Several interfaces are available that provide FSK keying from a computer USB port.

It is important to note that FSK transceiver inputs can only be used for modes that are based on binary FSK, typically with 170 or 200-Hz shifts. These modes include RTTY, PACTOR I and AMTOR. You cannot use the FSK input to transmit multi-frequency or phase-shift modulated signals such as MFSK16 or PSK.

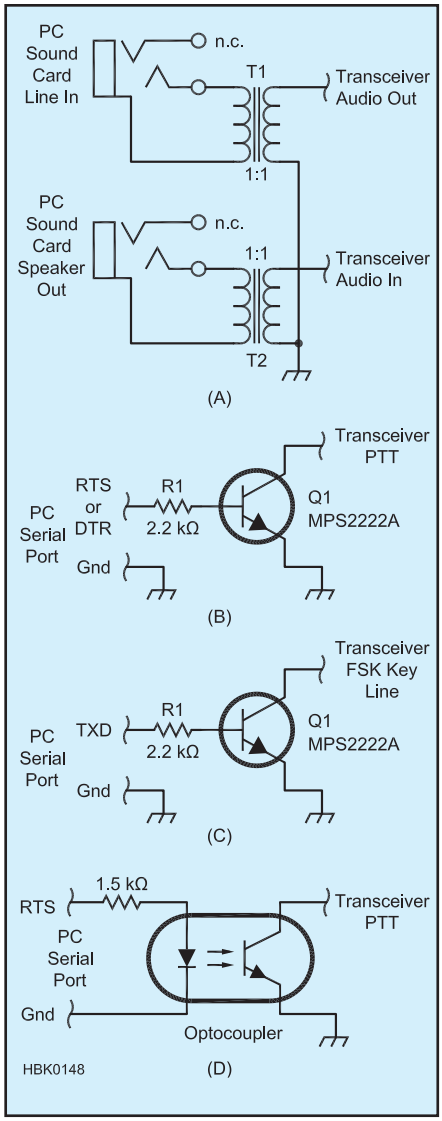

**Figure 2 — Some commonly used interface circuits. At A, isolating the sound device and transceiver audio lines. T1 and T2 are 1:1 audio isolation transformers. At B, a simple circuit to use the computer COM port to key your transceiver PTT, and at C, a similar circuit for FSK keying. Q1 is a general purpose NPN transistor (MPS2222A, 2N3904 or equivalent). At D, an optocoupler can be used to provide more isolation between radio and computer. On a DB9 serial port connector: RTS, pin 7; DTR, pin 4; TxD, pin 3; GND, pin 5.**

## 1.3 Transmit Audio Levels

When applying digitally modulated audio to a transceiver, it is critical to maintain proper levels. By overdriving the transceiver's audio input, you may create a wide, distorted RF signal that will be difficult, if not impossible, to decode at the receiving end. Such an overmodulated signal will also cause considerable interference on adjacent frequencies.

As you increase the transmit audio output from your sound device, pay careful attention to the ALC indicator on your transceiver. The ALC is the automatic level control that governs the audio drive level. When you see your ALC display indicating that audio limiting is taking place, or if the display indicates that you are exceeding the ALC "range," you are feeding too much audio to the transceiver.

Monitoring the ALC by itself is not always effective. Many radios can be driven to full output without budging the ALC meter out of its "nominal" range. Some radios become decidedly nonlinear when asked to provide SSB output beyond a certain level (sometimes this nonlinearity can begin at the 50% output level). We can ignore the linearity issue to a certain extent with an SSB voice signal, but not with digital modes because the immediate result, once again, is splatter.

The simplest method to tell if your signal is clean is to ask someone to give you an evaluation on the air. For example, PSK31 programs commonly use a waterfall audio that can easily detect "dirty" signals. The splatter appears as rows of lines extending to the right and left of your primary signal, as shown in **Figure 3**. (Overdriven PSK31 signals may also have a harsh, clicking sound.)

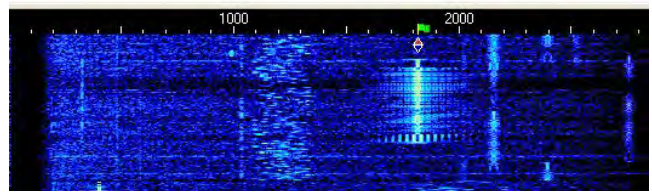

**Figure 3 — The waterfall spectrum display built into popular sound device software can help detect overdriven PSK31 signals. Note the lines extending from the signal on the right, near the 2000 Hz marker, indicating splatter. The other signals are from properly adjusted transmitters.**

If you are told that you are splattering, ask the other station to observe your signal as you slowly decrease the audio level from the sound device or processor. When you reach the point where the splatter disappears, you're all set.

Don't worry if you

discover that you can only generate a clean signal at, say, 50 W output. With PSK31 and most other sound device modes, the performance differential between 50 W and 100 W is inconsequential.

## 1.4 Sound Device Software

As you can see in **Table 1**, there is great deal of software available for sound-device-based digital modes. Some of the software applications are free, while others require registration and a fee.

There are applications dedicated to modes, such as *DigiPan* (PSK31) and *MMTTY* (RTTY). The trend in recent years has been to multimode programs that support many different digital modes in a single application.

Most software applications rely on *panoramic reception* where the software processes and displays all signals detected within the bandwidth of the received audio signal. The signal "signatures" are often shown within continuously scrolling *waterfall* displays such as the one shown in **Figure 4**.

Panoramic reception is particularly popular among PSK31 and FT8/FT4 operators because the narrow signals tend to cluster within a relatively small range of frequencies (about 2.5 to 3 kHz, the bandwidth of a typical SSB filter). By using panoramic reception, an operator can simply click the mouse cursor on one signal trace in the waterfall after another, decoding each one in turn.

The weakness of panoramic reception appears when wide IF filtering is used to display as many signals as possible. The automatic gain control (AGC) circuit in the receiver is acting on everything within that bandwidth, working hard to raise or lower the overall gain according to the overall signal strength. That's fine if all the signals are approximately the same strength, but if a very strong signal appears within the bandwidth, the AGC will *reduce* the gain to compensate. The result will be that many of the signals in the waterfall display will suddenly vanish, or become very weak, as the AGC drops the receiver gain. In cases where an extremely strong signal appears, *all* signals except the rock crusher may disappear completely.

The alternative is to use narrower IF or audio filter settings. These will greatly reduce the waterfall display width, but they will also remove or reduce strong nearby signals.

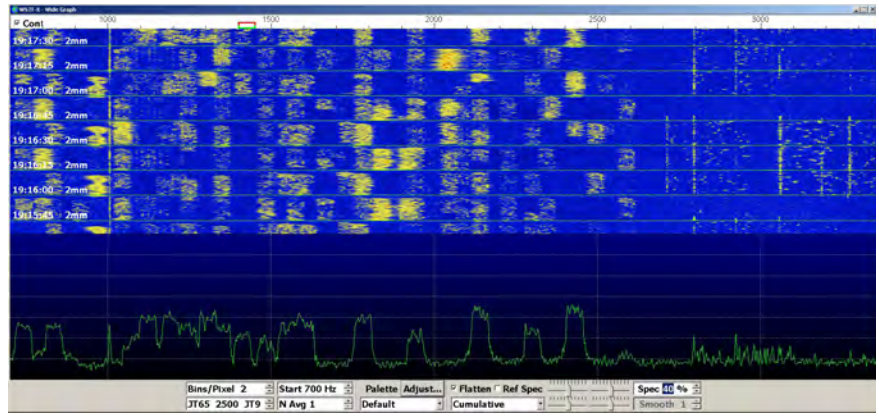

**Figure 4 — Many FT8 signals are visible in this view of a WSJT-X panoramic waterfall display.**

# 2 Packet Radio

Although the heyday of traditional packet radio has passed, it still survives in the form of networks devoted to specific applications such as emergency communication. A variant of packet radio also finds popular use in the Automatic Packet Reporting System (APRS), addressed in a later section.

## 2.1 The Packet TNC

In the beginning, there was *X.25*, a protocol for wide-area digital networks that typically communicated over telephone lines. X.25 works by chopping data into strictly defined *packets* or *frames* of information. Each packet is sent to the destination device where it is checked for errors. If errors are discovered, the packet must be sent again to ensure that received data is 100% error free.

In the early 1980s, amateurs began adapting X.25 for over-the-air digital communications. The result was *AX.25*. The new AX.25 protocol worked in much the same way, although it identified each message by sender and destination station call signs and added a Secondary Station ID (SSID) in a range from 0 through 15.

To create and decode these AX.25 packets, hams invented the *terminal node controller*, or *TNC*. TNCs do much more than assemble and disassemble data; they are miniature computers unto themselves. A TNC is also programmed to work within a radio network where there may be other competing signals. For example, to maximize the throughput for everyone on the same frequency, a TNC is designed to detect the presence of other data signals. If it has a packet to send, but detects a signal on the frequency, it will wait until the frequency is clear. TNCs also have a variety of user adjustments and other features, such as a mailbox function to store messages when the operator is away.

Regardless of the changes in packet radio, the TNC is still a vital component. In essence, a TNC functions as a "radio modem." It acts the middleman between your radio and your computer. The TNC takes data from your computer, creates AX.25 packets and then transforms the AX.25 formatted data into audio signals for transmission by the radio. Working in reverse, the TNC demodulates the received audio, changes it back into data, disassembles the AX.25 packets and sends the result to the computer.

For 300 and 1200-baud applications, TNCs create signals for transmission using AFSK. The most common is 1200 baud packet, used primarily at VHF. When creating a 1200-baud signal, a *mark* or 1 bit is represented by a frequency of 1200 Hz. A *space* or 0 bit is represented by a frequency of 2200 Hz. The transition between each successive mark or space waveform happens at a rate of 1200 baud. The frequencies of 1200 and 2200 Hz fit within the standard narrowband FM audio passband used for voice, so that AFSK is accomplished by simply generating 1200 and 2200 Hz tones and feeding them into the microphone input of a standard FM voice transmitter.

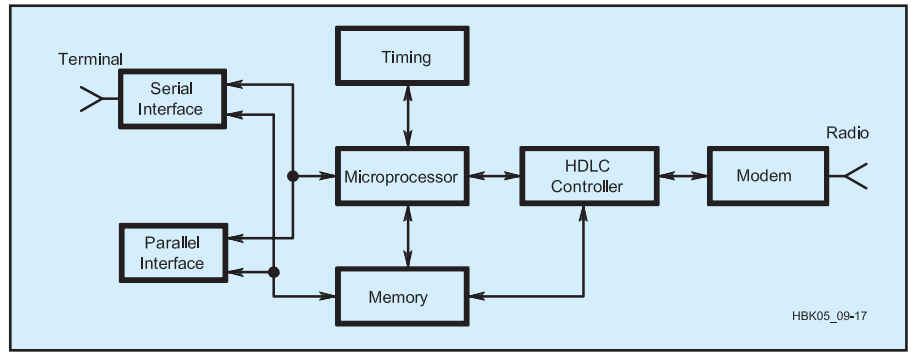

**Figure 5— A block diagram of a typical packet radio TNC.**

FSK, not AFSK, is used for 9600 baud packet. The data signal is filtered and encoded and then applied directly to the FM transmitter, after the microphone amplifier stage, through a dedicated port.

A block diagram of a typical TNC is shown in **Figure 5**. You'll note that it has a serial interface connecting to a "terminal." Most commonly, the terminal is a full-fledged computer running terminal software. Data flows to the computer and vice versa via this interface. At the heart of the TNC is the microprocessor and the attendant *High-level Data Link Controller*, or *HDLC*. The microprocessor is the brain of the unit, but the HDLC is responsible for assembling and disassembling the packets. The modem is simply that — a modulator (changing data to audio tones) and demodulator (changing audio tones back to data).

You can still find TNCs for sale from several manufacturers. There are also several transceivers with packet TNCs built in.

Another solution is a software TNC known as the *AGW Packet Engine*, or *AGWPE*, developed by George Rossopoylos, SV2AGW. The software is downloadable at **www.sv2agw.com/downloads**. With *AGWPE* and a sound device interface as described in this article, it is possible to operate packet radio without a hardware TNC — if your primary packet software application includes the ability to interface with *AGWPE*.

## 2.2 TNCs and Radios

Tones for 1200 baud can be fed directly into the microphone input of any VHF FM voice transceiver with an appropriate cable. Packet at 9600 baud requires an FM transceiver with a dedicated 9600-baud packet input, as noted earlier.

If you opt to craft your own cable, check your transceiver manual for the wiring diagram of the microphone jack. In most cases, there are separate connections for the audio input and the push-to-talk (PTT) line. (The TNC grounds the PTT line to key your transceiver.) Some transceivers also make receive audio available at the microphone jack for use with speaker/microphone combos. You can use this line to feed audio to the TNC. If it isn't available, you will have to make a separate connection to the transceiver's external speaker jack.

When you are setting up your TNC, be careful about the transmit audio level. Too high a level will create distorted signals that won't be decodable at the receiving station.

An easy way to check your transmitted signal is to use the TNC *calibrate* function. Get to the command mode (CONTROL-C) and enter **cmd: CALIBRATE**. Listen to your transmitted signal with another rig and raise the audio level from the TNC until the received volume seems to stop increasing. Now reduce the audio from the TNC until you can just hear a volume decrease in the receiver. Reduce it a bit more and you're done. Exit the calibrate function.

Some TNCs have an audio output adjustment on the board, some have an adjustment accessible through a hole in the side of the unit, and some have two fixed output levels selectable with a jumper. If one of these does not work, you may have to open the transceiver and find the mic gain control. If this is necessary, be sure you adjust the mic gain control and *not* the deviation control (which can change the bandwidth of your signal).

## 2.4 TNC Timing

The TNC's TXDELAY parameter specifies the delay interval between the time the TNC keys the radio and the time it starts send-

ing data. Normally 300-400 ms are adequate, but some transceivers take longer to settle after the keying line is triggered. If you have a problem being heard and your audio seems normal, try increasing TXDELAY to 400-600 ms.

On a busy network, packets and packet acknowledgements fly back and forth at a furious rate. One way to keep interference to a minimum is to manipulate the RESP and DWAIT parameters in conjunction with PERSIST and SLOTTIME to allow staggered transmissions.

RESP is the time delay between reception of a packet and transmission of an acknowledgement. DWAIT sets the delay between the time when activity is last heard on the channel and the moment your radio transmits. You should set values of RESP and DWAIT to the values recommended in your area (check with the person managing the local network or PBBS). Your TNC probably accepts a value in "counts" rather than in milliseconds, so don't forget to convert by the proper value to arrive at the correct timing value in milliseconds. For example, if you have been asked to set DWAIT to 600 ms and the units of DWAIT for your TNC are 10 ms per count, then you would command DWAIT = 60.

Most TNCs contain commands called PERSIST and SLOTTIME, which help enormously in avoiding interference. PERSIST sets the probability that a packet will be transmitted during a given time interval called a SLOTTIME. The parameter SLOTTIME governs the interval between transmission timing "slots." Initially, PERSIST should be set to approximately 64 and SLOTTIME to a value of about 10, which is equivalent to 100 ms.

FRACK (frame acknowledgement) should be set to 6 and RETRY to 10. FRACK sets the number of seconds between retries and RETRY sets the number of times your TNC will try to send a packet and gain acknowledgement of it before it gives up and disconnects

### 2.5 Monitoring

Start by listening to an active packet frequency in your area. With the radio cable connected, turn on your radio and increase the receiver volume partway. Some TNCs include an LED indicator that shows that the TNC is receiving audio. Turn up the squelch control on the radio until the LED is extinguished. Tune the rig to any odd numbered frequency between 144.91 and 145.09, or between 145.61 and 145.79 MHz, and set the rig for simplex operation. Your best bet may be to search for a DX PacketCluster, or try monitoring APRS activity on 144.39 MHz. When you hear the buzzing packet signals and see text on your screen, you'll know you've hit the jackpot.

Depending on the type of activity you are monitoring, you may see what appears to be nonsense. If you are monitoring APRS, you'll see strings of numbers. These are latitude/longitude position reports. On PacketClusters, you'll see DX call signs and frequencies.

### 2.6 "Connected" vs "Unconnected"

When discussing TNCs and networks, it is important to understand the difference between connected and unconnected communication.

If you are simply monitoring local packet transmissions, your TNC is in an *unconnected* state. What you see is what you get. If a signal is garbled by noise or interference, you'll see nothing on your screen (unless you've enabled the PASSALL function, in which case you'll see gibberish). If you transmit an unconnected packet, the signal simply leaves your antenna destined for nowhere in particular. Some stations may decode it, some may not.

When your TNC is operating in a *connected* state, everything changes. When you are connected, your station is linked to another station in a "virtual" sense. In a connected state, every packet you send is intended specifically for the receiving station (even though others can see it).

When your TNC transmits a packet, it starts a countdown clock. If the clock reaches zero before your TNC receives an acknowledgement (known as an *ACK*) that the packet arrived without errors, it will send the same packet again. When the packet is finally acknowledged, the TNC will send the next packet. And so it goes, one packet after another. The operator at the other station may also be sending packets to you since this communication process can flow in both directions simultaneously.

The big advantage of the connected state is that data is delivered error-free. One packet station can connect to another directly, or through a series of relaying stations. Error-free can be a disadvantage, too. Specifically, a connected state works best when signals are strong and interference is minimal.

Remember that if too many packets are lost — by either not arriving at all or arriving with errors — the link will fail. That's why AX.25 packet radio tends not to work well on the HF bands. With all the noise, fading and interference, packets are often obliterated in route.

Unconnected packets are ideal for applications where you are transmitting essentially the same information over and over. Since unconnected packets can be decoded by any station, they are an excellent means of disseminating noncritical data (data that doesn't need guaranteed error-free delivery) throughout a given area. If a station fails to decode one packet, it merely waits for the next one. APRS uses exactly this approach.

# 3 The Automatic Packet Reporting System (APRS)

The Automatic Packet/Position Reporting System, better known as *APRS* (**aprs.org**), is the brainchild of Bob Bruninga, WB4APR. In fact, APRS is a trademark registered by WB4APR. The original concept behind APRS involved tracking moving objects, and that's still its primary use today. However, APRS has been evolving to become an amateur network for other applications such as short text messaging, either from ham to ham, or between hams and non-hams through APRS internet gateways.

Mobile APRS stations communicate their positions based on data provided by on-board Global Positioning System (GPS) receivers. The GPS receivers are attached to either packet radio TNCs or simplified packet devices known as *position encoders*, which in turn are connected to transceivers (see **Figure 6**). At receiving stations, various APRS software packages decode the position information and display the results as icons on computer-generated maps such as the one shown in **Figure 7**. When a station moves and transmits a new position, the icon moves as well.

Virtually all APRS activity takes place today on 144.39 MHz using 1200-baud packet TNCs and ordinary FM voice transceivers. In areas where the APRS network is particularly active, you may hear traffic on 445.925 MHz as well. There is also some activity on HF.

### 3.1 Setting Up an APRS Station

If you own a 2-meter FM voice transceiver, you already have the primary component of your APRS station. Tune your radio to 144.39 MHz and listen for packet transmissions. If you hear them, it means you have APRS activity in your area. To decode APRS packets,

**Figure 6 — A 2-meter FM handheld transceiver attached to an APRS position encoder.**

**Figure 7 — A snapshot of APRS activity using *UI-View* software. Note the icons representing various mobile and fixed stations.**

you'll need a TNC, or a transceiver that has a TNC built in.

There are several packet-ready transceivers that also have built-in GPS receivers. However, if all you want to do is monitor APRS activity, you do *not* need a GPS receiver. If you want to participate in the local APRS network from a fixed (non-moving) station such as your home, you still do not need a GPS receiver. Just determine your home latitude/longitude coordinates and you can use them to establish the location of your home station on the network. There are numerous sites on the internet that will convert your home address to a correct latitude and longitude.

The final component of your APRS station is software. You'll need software to display the positions of APRS stations, along with other information contained in their transmissions. APRS software is also essential if you want to communicate over the APRS network from a fixed or portable station. Note, however, that APRS software is *not* necessary for mobile stations that wish to merely transmit APRS beacons for tracking purposes. That function is carried out automatically using the GPS receiver and APRS-compatible TNC or tracking device; it does not depend on software.

The most popular APRS Windows program is *UI-View*. *UI-View* was created by the late Roger Barker, G4IDE. You'll find it online at **www.ui-view.net/**. The 16-bit version is free for downloading. To use the 32-bit registered version, hams are asked to donate to their local cancer charities. Details are available on the *UI-View* website. Another worthwhile program for Windows is PinPoint APRS, which you will find at **www.pinpointaprs.com**. For the Macintosh, there is *MacAPRS* available from **www.winaprs.com**. For Linux there is *Xastir*, available for download at **sourceforge.net/projects/xastir/**.

APRS software, regardless of the operating system, is designed to talk to the packet TNC, processing the incoming APRS data and creating icons on your computer screen. The application also uses the TNC to transmit APRS data. This means that the software and the TNC must communicate with each other at the same baud rate. Every APRS application has a setup menu to program the correct parameters for various TNCs.

Depending on the software, there may be other features such as logging or messaging. APRS software changes rapidly, so check the help file or manual for specific instructions.

## 3.2 Maps and APRS

No matter which APRS software you choose, one critical aspect is the mapping function itself. To get the most from APRS, your software maps must be as comprehensive as possible, preferably with the ability to show detail down to street level.

Downloadable APRS software applications generally do not come with detailed maps. Detailed map files are numerous and large, impractical to bundle with every APRS program. Instead, most applications are designed to import user-created custom maps, or to work with existing commercial mapping programs such as Microsoft *Streets*, Delorme *Street Atlas* and *Precision Mapping*.

*UI-View*, for example, can automatically load and display maps from *Precision Mapping*. You must purchase and install *Precision Mapping* on your PC, then download and install a small *Precision Mapping* "server" application into *UI-View*.

Each APRS transmission includes characters that define the type of map icon that will be displayed at the receiving end. If you are operating a fixed station, your APRS software will allow you to choose your icon. If you are a mobile station using a traditional TNC, you'll need to define your chosen icon in your beacon statement. APRS-compatible TNCs give you the ability to do this. APRS position encoders also allow you to choose your icon when you program the unit. Your mobile icon might be a car, boat or airplane.

## 3.3 APRS Position Encoders

If you aren't blessed with a transceiver that offers a built-in TNC and GPS receiver, you can create a mobile APRS station with any VHF FM transceiver, a TNC and a GPS receiver. Wire everything together, connect an antenna and dc power and you're set. For hams on the go, however, it's common to replace the full-fledged TNC with an APRS *position encoder*, also referred to as an APRS *tracker*. A position encoder is a compact device designed for one purpose: to receive data from the GPS receiver, assemble APRS packets from the data and create modulated signals for use by the transmitter. Some position encoders include GPS receivers in their designs. You'll even find position encoders that are complete packages incorporating tiny

GPS receivers and low power FM transmitters.

To use a position encoder, you must program it the same way that you initially program a TNC. Like TNCs, position encoders connect to computer serial or USB ports for programming and most come with their own programming software. You must enter your call sign and other information such as your beacon interval (how often you want the position encoder to transmit your position). Most position encoders allow you to set the beacon interval to a certain amount of time (say, every two minutes). Some position encoders can be configured to transmit position beacons after a certain distance (every mile), or whenever the vehicle turns a corner.

## 3.4 APRS Networking Tips

One of the key features of APRS is that while it uses AX.25 to transport its messages, it essentially ignores all the AX.25 connection-oriented baggage. Unlike traditional packet radio, APRS stations do not establish "connections" with each other. Instead, APRS packets are sent to no one in particular, meaning to *everyone*.

Every APRS station can function as a digital repeater, or *digipeater*. So, if it receives a packet, it will retransmit the packet to others. As other digipeaters decode the same packet, they will also retransmit and spread it further. This is known as *flooding* and is illustrated in **Figure 8**.

As an APRS user, you can set up your station to address its packets through specific digipeaters according to their call signs. But when you're traveling, how do you determine which digipeaters you should use?

### PATHS AND ALIASES

In the packet world, nodes and digipeaters can have *aliases*. A digipeater call sign may be W1AW-1, but it can also carry an alias, using the MYALIAS command in the digipeater TNC. Perhaps the digipeater alias would be NEWNG (meaning the ARRL HQ home town of Newington). You can route packets through the digipeater by addressing them to W1AW-1, or simply by addressing them to NEWNG. Any station that is set up to respond to an alias can handle your packets automatically, even if you don't know its call sign.

Unlike typical packet use of aliases in which a given single station has a specific alias, APRS specifies standard digipeater aliases that nearly all stations use. This means that you can travel anywhere in the country and still participate in the APRS network without knowing digipeater call signs. (Otherwise, you'd have to reconfigure your TNC whenever you moved from one area to another.)

The most common APRS digipeater alias is *WIDEn-N*. The letters "n" and "N" represent numbers. The first (left-most) "n" designates how many WIDE digipeaters will relay your packets, assuming they can receive them. WIDE2, for instance, is the same as saying that you want your packets relayed through *two* WIDE digipeaters. The second "N" is the *Secondary Station Identifier* (SSID). The SSID is used in APRS networks as a means of limiting how often (and how far) a packet can be repeated.

Here's how it works. Each time your packet traverses a WIDEn-N digipeater, the digipeater subtracts 1 from the SSID as it retransmits. The next digipeater deducts 1 and so on until the SSID reaches zero, at which time the packet will not be repeated. This has the effect of limiting the flood radius. See **Figure 9**.

When you configure a TNC or position encoder for use with APRS, you can use these aliases to set up the paths for the beacon packets you'll be transmitting. In most devices this is accomplished with the UNPROTO parameter, sometimes simply referred to as the "Path." If you are a fixed station (a station at home, for instance), set your path as **WIDE2-2** (or with a traditional TNC UNPROTO statement, set it to APRS VIA WIDE2-2). This designates that your reports will be relayed by *two* WIDEn-N digipeaters and limits the spread beyond those repeaters to just two retransmissions. Set your TNC to beacon once every 30 minutes. That's enough for a fixed station.

If you are running APRS from a car, try **WIDE1-1,WIDE2-1** (or APRS VIA WIDE1-1,WIDE2-1). WIDE1-1 ensures that your packet will be picked up by at least one local digipeater or a home station acting as a fill-in digipeater and relayed at least once. WIDE2-1 gets your packet to another, presumably wider-coverage digipeater, but limits the retransmissions beyond this point. It's wasteful of the network to set up wide coverage for a station that is rapidly changing its position

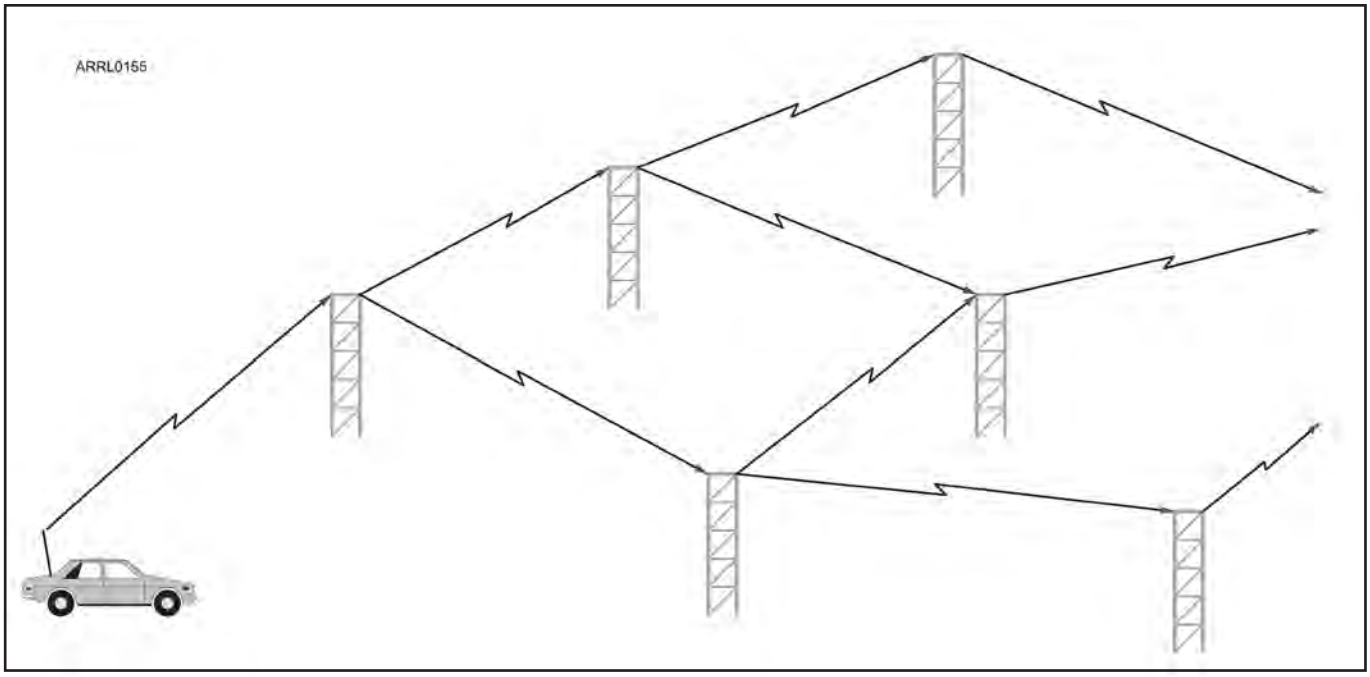

**Figure 8 —In this example, an APRS packet is transmitted by a mobile station and is retransmitted by a nearby digipeater. Depending on how the mobile operator configured his TNC or tracker's path, the packet will be picked up and repeated by several other digipeaters. This is known as flooding.**

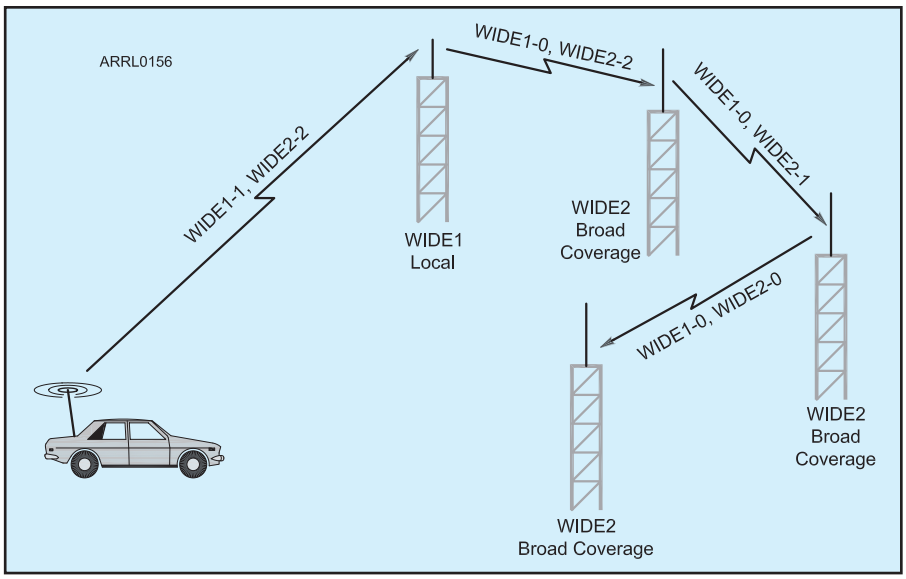

**Figure 9 — By using the WIDEn-N system, we can limit packet flooding in a local network and greatly reduce congestion. The mobile station in this example has his path set as WIDE1-1,WIDE2-2. Notice how his packet propagates through the network and how the SSID number is reduced by one each time the packet is repeated through a digipeater with a corresponding alias. When it reaches the third WIDE2 digipeater, the counters all reach zero and digipeating stops.**

anyway. Mobile stations that are in motion should also limit their beacon rate to once every 60 seconds, or once per mile, whichever comes first.

Never invoke extremely wide coverage, such as a WIDE5-5 path, unless you are way out in the hinterlands and need every relaying station available to get your packets into the network.

Another popular alias is the "single state" — SSn-N — to limit the spread of your packets to a specific state or area within a state. To keep packets within the state of Connecticut, for example, you could use the SSn-N alias in a path statement, like this: CT1-1, CT2-2. This path assures that local Connecticut stations (CT1-1) will repeat the packets, and that broad-coverage stations (CT2-2) will relay them throughout a large portion of the state. APRS digipeaters outside Connecticut, however, will not respond to these packets because they won't recognize the CT2-2 alias (although they will recognize an alias for their state). The packets will still be heard across state borders but will not be digipeated or add to the packet activity in a neighboring state.

# 4 PACTOR

PACTOR is a type of HF digital communication that, unlike many other HF modes, offers error-free text and file transfers. PACTOR communication resembles packet radio in that it establishes a "link" between two stations. Data is sent in discrete frames and each frame is acknowledged by the receiving station. This rapid back-and-forth exchange creates PACTOR's distinctive *chirp-chirp-chirp* signal. Through robust coding and sophisticated modulation techniques, PACTOR is often able to maintain the link even in the face of significant noise, fading and interference.

PACTOR I, introduced in the early 1990s, has been largely superseded by PACTOR II and III, which provide faster throughput in difficult conditions. Both PACTOR I and II generate signals that occupy 500-Hz bandwidths. PACTOR III offers even more efficient communication, but its signal occupies a bandwidth in excess of 2000 Hz.

The most recent version of PACTOR is PACTOR IV, which offers much greater throughput even when compared to PACTOR III. However, at the time this was written, FCC rules did not permit signaling rates greater than 300 baud below 28 MHz and PACTOR IV exceeds this limit. The ARRL has petitioned the FCC to change the rules to permit the use of higher signaling rates below 28 MHz, but at the time of this writing, the FCC had yet to act.

To set up a PACTOR station, you must purchase a stand-alone multimode controller that includes the PACTOR mode. Controllers manufactured by Kantronics (**www.kantronics.com**) and Timewave (**www.timewave.com**) include PACTOR I. For PACTOR II or III, you must purchase a controller made by Special Communications Systems (**www.scs-ptc.com**), the original developers of PACTOR.

**Figure 10** illustrates a typical PACTOR station built around a multimode controller. The computer is functioning only as a dumb terminal for the controller in this application, so it does not have to be particularly powerful. All that is required is basic terminal software as described in the section on packet TNCs. More sophisticated software applications can provide a smoother, easy-to-use interface, but these require more capable computers.

A PACTOR station requires an SSB transceiver capable of switching from transmit to receive within approximately 30 ms. Most modern HF transceivers can meet this requirement, but not all. *QST* magazine Product Reviews test this specification for all HF transceivers. The transmit audio supplied by the controller can be fed to the microphone or accessory jack to operate AFSK, which is the standard procedure, although PACTOR I can also operate using FSK.

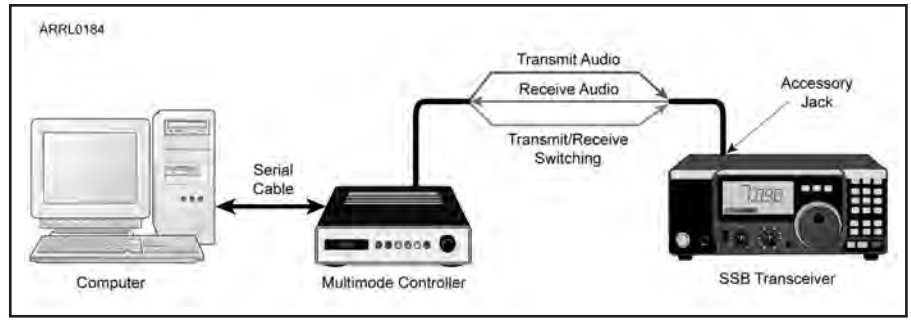

**Figure 10 — A PACTOR station with a multimode controller. For PACTOR II and III operation, the controller must be a model manufactured by the SCS Corporation.**

# 5 High Speed Multimedia (HSMM)

Wireless networking using IEEE 802.11 standards has seen explosive growth during the last several years. Coffee shops, fast-food restaurants, hotels, airports and many other high-traffic locations now include wireless internet (WiFi) hotspots. Some hotspots offer free internet access while other charge an access fee, payable with your credit card.

Wireless networks are also popular at home. Establishing a home network is as simple as installing a *wireless router* to manage the data flow from the broadband internet connection. The router allows one or more traditional desktop computers to tap the broadband connection through wired (usually Ethernet) access while simultaneously making the internet available wirelessly to one or more laptops.

All these home networking devices — routers, wireless access cards, and so on — are unlicensed FCC Part 15-regulated transceivers with RF outputs measured in milliwatts. A number of their channel frequencies overlap two amateur radio bands: 2.4 and 5.8 GHz. This means that hams can put them to work as "transceivers" under our Part 97 rules. See **Table 2** for specific frequencies.

By using consumer-grade routers, low-loss coaxial cable and gain antennas, hams can quickly establish high-speed, long-distance wireless networks on these 2.4 or 5.8 GHz frequencies. This type of operating is referred to as *high speed multimedia*, or *HSMM*.

With HSMM amateurs can operate several different modes at the same time, and usually do. HSMM is generally IP-based, and given enough bandwidth, radio amateurs have the capability to do the same things with HSMM that are done on the internet.

- *Audio*: This is technically digital voice, since it is two-way voice over an IP (VoIP) network similar to EchoLink and IRLP networks used to link many amateur radio repeaters over the internet. (VoIP is covered in a later section.)
- *Video*: Motion and color video modes, are called amateur digital video (ADV). This is to distinguish it from digital amateur television (DATV). DATV uses hardware digital coder-decoders (CODEC) to achieve relatively high-definition video like *entertainment quality TV*. The usual practice in HSMM radio is to use a far less expensive (often free) PC-based software video codec to achieve *video communications quality* signals in much smaller bandwidths.
- *Text:* Text exchanges via a keyboard are often used in HSMM radio, but they are similarly called by their internet or packet radio name: *Chat mode*, and if a server is available on the network, e-mail can also be exchanged.
- *Image*: Image file transfers using file transfer protocol (FTP) can also be done, just as on the internet.
- *Motion video*: FTP of MPEG files can provide one-way video streaming of short video clips.
- *Remote control*: Individual devices or even complete stations can be remotely controlled.
- *Mesh networking*: A mesh is a wireless cooperative communication infrastructure in which each station functions as a relay, allowing the entire network to cover a large area. See **Figure 11**. This type of infrastructure can be decentralized (with no central server) or centrally managed (with a central server). Both are relatively inexpensive and very reliable. Individual mesh stations (nodes) act as repeaters to transmit data from nearby nodes. The reliability comes from the fact that each node is connected to several other nodes. If one node drops out of the network, due to hardware failure or any other reason, its neighbors simply find another route. Capacity can be increased by simply adding more nodes. Mesh networks constructed using HSMM nodes are known as *HSMM-MESH* or *Broadband-Hamnet* (**www.broadband-hamnet.org**).

## 5.1 A Basic HSMM Radio Station

For the sake of simplicity, we'll discuss an HSMM setup with two stations operating in a host/client configuration. See **Figure 12**.

At the time of this writing, one of the most popular wireless router for HSMM applica-

**Table 2**
**Wireless Network Frequencies in Amateur Bands**

| *Channel* | *Center Frequency* |
|---|---|
| 1 | 2.412 GHz |
| 2 | 2.417 GHz |
| 3 | 2.422 GHz |
| 4 | 2.427 GHz |
| 5 | 2.432 GHz |
| 6 | 2.437 GHz |
| *Channel* | *Center Frequency* |
| 132 | 5.660 GHz |
| 136 | 5.680 GHz |
| 140 | 5.700 GHz |
| 149 | 5.745 GHz |
| 153 | 5.765 GHz |
| 157 | 5.785 GHz |
| 161 | 5.805 GHz |
| 165 | 5.825 GHz |

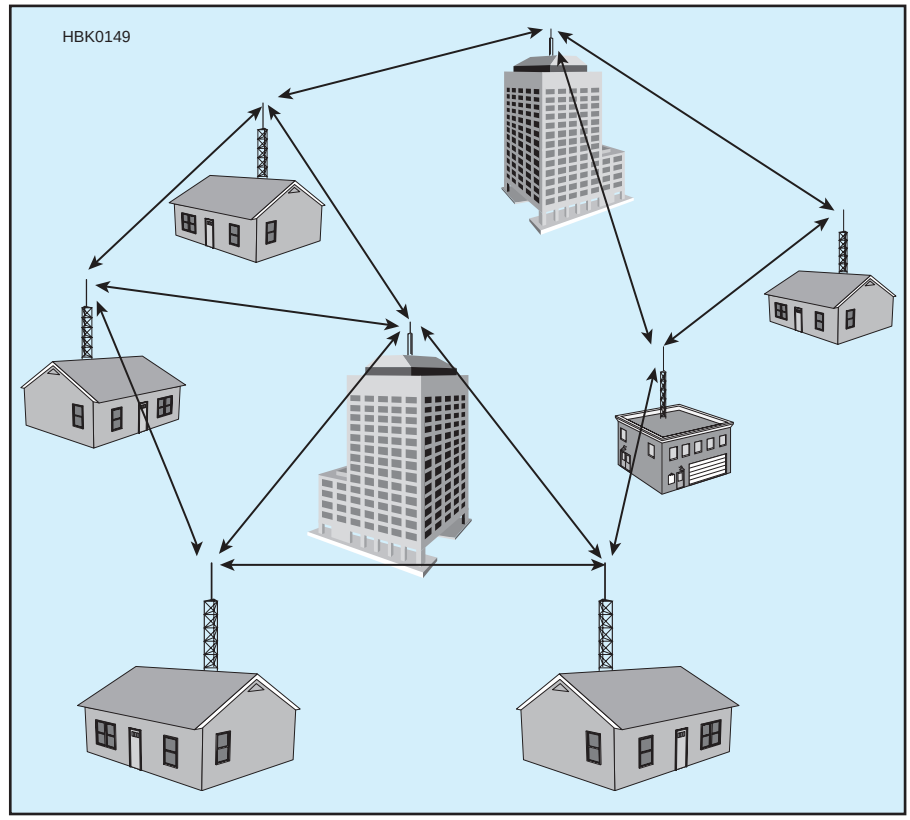

**Figure 11 — An HSMM Mesh, or Broadband-Hamnet, network is highly decentralized. Individual mesh stations (nodes) act as repeaters to transmit data from nearby nodes. If one node drops out of the network, the other nodes will automatically re-route the traffic.**

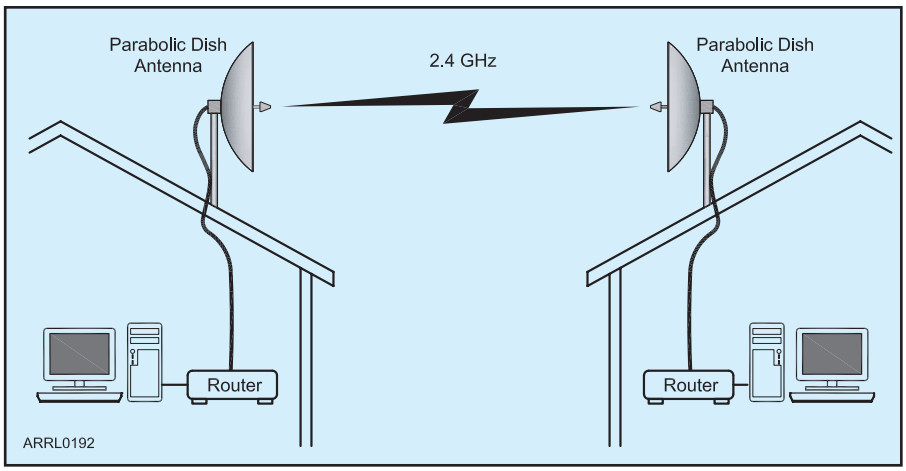

**Figure 12 — This is a simplified diagram of a typical HSMM link between two stations. Note that high gain parabolic dish antennas are being used in this example.**

**Figure 13 — RP connector adapters.**

tions is the Linksys model WRT54GL. It is a combination unit consisting of a wireless access point (AP) or hub coupled with a router. As with other routers, your host PC or laptop connects directly to it using a standard Ethernet cable. If the PC is also connected to the internet, then it may also perform the function of a *gateway*.

The WRT54GL is a Linux-based model that supports firmware upgrades. HSMM-active amateurs have been creating their own WRT54GL firmware to support special applications (such as mesh networking). They are effectively "modifying" the WRT54GL in ways Linksys could not have imagined! You do not have the use a WRT54GL to explore HSMM, however. Any wireless router will do. The advantage of the WRT54GL is only that it is widely available and easily modifiable.

The first step in configuring your router for HSMM is to disconnect both flexible antennas that came with the unit and replace them with a high-gain directional antenna system. To connect a gain antenna, you are going to be become familiar with RP (reverse polarity) connectors. These connectors appear to be male connectors on the outside, but they have a socket rather than a pin for the center conductor. RP connectors are used by the manufacturers to discourage Part 15 owners from using the equipment in ways for which it was not WiFi certified.

As licensed radio amateurs, we can modify the system to accomplish our specific requirements within the amateur bands. To connect coaxial cable for an external antenna, you can use an adapter or short jumper cable assembly with appropriate connectors. The adapter shown in **Figure 13** has an RP connector on one end and a standard SMA connector on the other.

There are often two antenna ports on wireless devices. These are used for *receive space diversity*. The wireless device will normally automatically select whichever antenna is receiving the best signal at any specific moment. Which do you connect to?

The transmitted signal from the wireless router always goes out the same antenna port. It does not switch. In other words, most wireless devices use space diversity on the receive side and not on transmit. Some access points/wireless routers will allow you to manually (via software) select the antenna port that is used for transmission. When there is no obvious choice, you will need to find some means of detecting which antenna is the transmit antenna port with RF output power present. That is the port to connect to your gain antenna.

Be sure to use low-loss coaxial cable, and keep the run as short as possible. Coaxial cable loss at these frequencies can be quite high, so you are often better off mounting the router directly at the antenna, connecting to it through a very short length of cable. From there you can run the Ethernet cable back to your computer.

## SOFTWARE CONFIGURATION

You will need to use either the network configuration software from the router manufacturer or the configuration tool that is part of your operating system. Some routers offer user-friendly access through internet browsers, which is particularly convenient. Regardless of the approach, the goal is to access and change your router's settings.

*SSID*: The AP/wireless router host software is provided with an *SSID* (Service Set Identifier) that many Part 15 stations turned off for somewhat higher security. But radio amateurs should leave it **ON**. Enter your call sign as the SSID and use it for the station identification. It constantly broadcasts your call thus, providing automatic and constant station identification. There are 32 characters available for use in this field so more information such as your group's name can be entered too, including spaces and punctuation. If the router asks if you want to enable the broadcast, click **YES**. (Note that SSID in the HSMM world has a somewhat different meaning than SSID in the packet radio community. Among packet users, SSID is defined as Secondary Station Identifier.)

*ESSID*: Some manufacturers use this term in place of SSID to put emphasis on the fact that the SSID is the name for your *network*, not for a specific wireless AP/router.

*Access Point Name*: When this field is made available (by default is it blank) it is for you to enter a description. This may be handy if you have deployed more than one AP in your network all with your call sign as the SSID. It would allow you to tell them apart. Otherwise, just leave it blank.

*Channel*: To avoid interfering with other services as much as possible, we need to also look at channel selection. Most HSMM activity is concentrated on 2.4 GHz, using channels 1 through 6, which are within the 2.4 GHz ham allocation.

It is probably best to avoid channel 6. It is the most common manufactures default channel setting and 80% or more of your neighbors will be using it for their household wireless local area network (WLAN). Channel 1 is used by most of the remaining manufacturers as their default channel, so avoid that too. The result is most radio amateurs use channels 3 or 4 depending whether there is a WISP (Wireless Internet Service Provider) operating in their area. Often a WISP will use one of these intermediate channels with a highly directive antenna for back-haul or other purposes. If so, you may wish to coordinate with the WISP and arrange to use some other channel rather than the one specifically used by the WISP. It is not a perfect solution because

of all the overlap, but it is a good faith effort to keep most of your stronger signal out of anyone's home, business or governmental WLAN traffic.

*WEP*: This stands for Wired Equivalent Privacy. Despite all the horror stories you may have read in the press, this encryption method provides more than adequate means to economically achieve authentication and thus keep most freeloaders off your network. If you live in the country, you may not need to enable this capability. In an urban environment, it is probably a good thing to do so that you need not constantly monitor every bit of traffic coming over the network to ensure that it originates from an amateur radio station. Mixing traffic with another service that shares the same frequency band is not a generally accepted practice except in times of emergency. Therefore, it is often necessary for HSMM radio stations to encrypt their transmissions. This is not to obscure the meaning of the transmission or hide the information. In amateur HSMM applications, the purpose of using WEP is only to block access by non-hams. Amateur HSMM networks openly publish their encryption keys for other hams to use.

Most wireless routers will allow for the use of multiple WEP keys, typically up to four. This will allow you to configure the device so that different client stations have different access authority. For example, club members may have one level of access, while a visiting radio amateur may be given a lesser access. Most HSMM radio groups have just one WEP key and everybody gets that one.

Remember that when it comes to the length of the WEP or other key used, our main purpose is to provide a simple and economical means of authentication already available on the wireless devices. In other words, it is to ensure that only Part 97 stations and not Part 15 stations auto-associate or auto-connect with our HSMM radio node. The shorter the WEP key, the better. This makes it easy to use and remember. During early HSMM radio experimenting around the year 2000, the shortest possible key (5 characters) was used: HSMM-

*Authentication Type*: Some routers will ask for the type of authentication you want to use such as *shared key*, *open system*, and *both*. Click on **SHARED KEY** because you will be sharing the WEP/WPA key with all radio amateurs who wish to access your HSMM radio node.

*DHCP*: Some routers will ask if you want Dynamic Host Configuration Protocol enabled. This is the function that assigns IP addresses. Unless you have another source of the DHCP function on your network, you will want to **ENABLE** this function.

*Antenna Selection*: A few wireless routers with dual antennas will ask you select an antenna. The default is normally receive space diversity. Because we are going to connect an outside gain antenna, you want to make a selection. Otherwise, you will need to identify which antenna is the actual transmit antenna and connect the feed line to that port, as discussed previously.

*Mac Address Filter*: Some wireless routers will allow for this security measure, but it is troublesome to administer it, so it is recommended that you not bother enabling this function. Use WEP or some other method of encryption using the guidelines discussed previously.

*Output Power*: Some wireless routers will allow you to set this power level, often up to 100 mW. As with all other radio amateur operations use only the minimum power needed to accomplish your mission.

### THE FAR END OF THE LINK

The computer at the client end of the HSMM link need only have a wireless networking adapter, not a separate router. These transceivers/wireless adapter cards usually come in three forms:

1) One form is called a PC card. Earlier these were called PCMCIA cards, but more recent terminology is to simply call them laptop PC cards.

2) Another type of transceiver/adapter comes with a USB interface, such as the one shown in **Figure 14**. This is often considered a superior interface for most HSMM stations. The reason for this has nothing to do with the quality of the transceiver, but rather the fragile nature of the tiny connectors found on PC cards. They are not really designed for frequent plugging and unplugging. Without extreme care, they can be easily torn out.

3) Linksys and other manufactures also produce similar cards for the expansion slot on the rear of your desktop PC too.

**Figure 14 — At the client end of the HSMM link, a simple wireless transceiver/adapter will do.**

Regardless of the device you choose, it must have an antenna that is removable or has an external antenna port of some type.

To connect to the AP/wireless router in an HSMM radio network, the wireless computer user(s) at the far end must exit ad-hoc mode and enter what is called the *infrastructure mode*, in their operating software. Infrastructure mode requires that you specify the radio network your computer station is intended to connect to (the host station's call sign), so set your computer to recognize the SSID you assigned to the AP/wireless router to which you wish to connect.

As described previously, you may need to use an adapter to connect the card or interface antenna connector to the coaxial cable running to the antenna. At the other end, most 2.4 GHz antennas come with a standard female N-series connector.

Team up with a nearby radio amateur to test. Do your initial testing in the same room together making sure the link-up is working. Then as you increase distances going toward your separate station locations, you can coordinate using a suitable local FM simplex frequency. You will increasingly need this communication to assist with directional antenna orientation as you get farther apart.

## 5.2 Running High Power

It is tempting for some radio amateurs to think that if they run higher power, they will get better range out of their HSMM radio station. This is not always the case. There are many factors involved in range determination when operating at 2.4 or 5.8 GHz. The first and most significant of these is the lay of the land (topology) and path obstructions. Running additional power is unlikely to correct for either of these impediments.

Second, running higher power to improve signal link margins often requires that this be done at both ends of the link to obtain meaningful results.

Third, most RF amplifiers for use with 802.11 are of the BDA (bidirectional amplifier) type, such as the one shown in **Figure 15**. They amplify both the incoming signal and the outgoing signal, and to get maximum effectiveness out of such devices they must be mounted as close as possible to the antenna.

Fourth, 802.11 signals from such inexpensive broadband devices often come with significant sidebands. This is not prime RF suitable for amplification. A tuned RF channel filter should be added to the system to reduce these sidebands and to avoid splatter.

Also, if your HSMM radio station is next door to an OSCAR satellite ground station or other licensed user of the band, you may need to take extra steps to avoid interfering with them, such as moving to channel 4 or even

**Figure 15 — A 2.4 GHz bidirectional amplifier.**

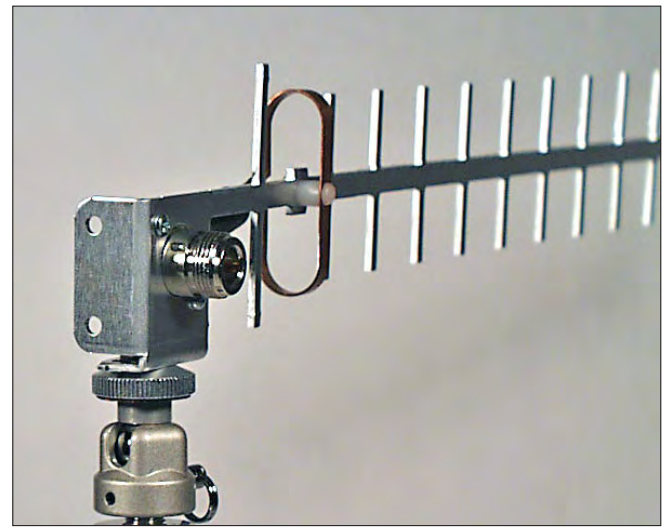

**Figure 16 — Directional antennas, such as this MFJ 2.4 GHz Yagi, are best for HSMM links.**

channel 5. In this case a tuned output filter may be necessary to avoid not only causing QRM, but also to prevent some of your now amplified sidebands from going outside the amateur band, which stops at 2450 MHz.

Do not use higher power as a substitute for higher antenna gain at both ends of the link. Add power only after all reasonable efforts have been taken to get the highest possible antenna system gain and directivity.

### 5.3 HSMM Antenna Options

There are several factors that determine the best antenna design for a specific HSMM radio application. Most commonly, HSMM stations use horizontal instead of vertical polarization because it seems to work better. In addition, most Part 15 stations are vertically polarized, so this is sometimes thought to provide another small barrier between the two different services sharing the band. With multipath propagation is it doubtful how much real isolation this polarization change provides.

More importantly, most HSMM radio stations use highly directional antennas (**Figure 16**) instead of omnidirectional antennas. Directional antennas provide significantly more gain and thus better signal-to-noise ratios, which in the case of 802.11 modulations means higher rate data throughput and greater range. Higher data throughput, in turn, translates into more multimedia radio capability. Highly directional antennas also help amateurs avoid interference from users in other directions.

## 6 Automatic Link Establishment (ALE)

*Automatic link establishment* (*ALE*) is a "system" that incorporates digital techniques to establish a successful communications link. ALE is not a digital mode *per se*, but the primary software is sound device based.

To understand ALE, consider how HF propagation changes. A band can open over a path one hour, but close the next. A signal may be fully readable on one band, but inaudible on another. With that in mind, imagine two stations, one in New York City and one in Los Angeles, that wish to communicate on the HF bands (see **Figure 17**). Basic propagation guidelines give a general idea of which bands might be best, but operators at both ends of the path will have to experiment, calling on several bands until they find a frequency that supports a transcontinental path.

ALE automates this process, allowing the stations under computer control to automatically call each other on different bands until contact is established. In the example, the operator in New York City initiates the ALE call by entering the call sign of the receiving station into his ALE software, along with some likely frequencies. The call sign becomes the *Selective Call*, or SELCAL. The ALE software switches the transceiver to the first frequency in the queue and transmits the chosen SELCAL. If there is no response, the software will step the transceiver to another frequency and try again.

At the same time, the receiving station in Los Angeles has been automatically scanning specific ALE frequencies, listening for its call sign. When it finally decodes something that resembles its call sign, it stops scanning and listens since the ALE data burst contains several repetitions of the call. When it finally decodes its full call sign, the Los Angeles

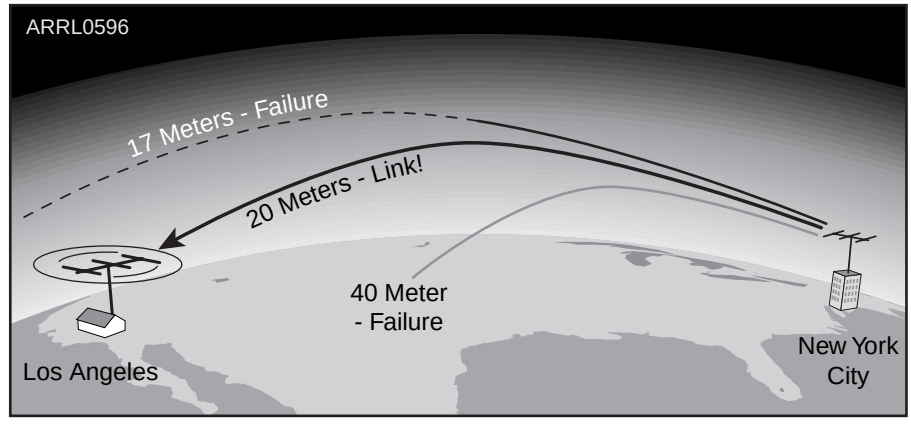

**Figure 17 — The ALE calling station typically scans through a list of frequencies, calling on each one until a path to the receiving station is found.**

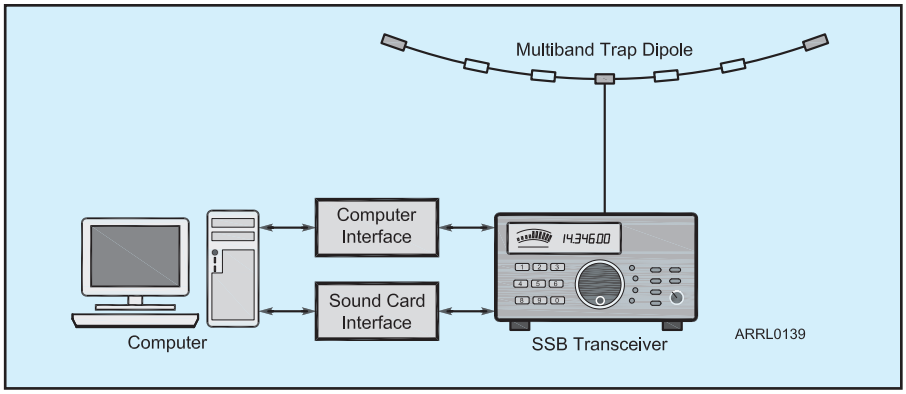

**Figure 18 — An optimum ALE station has a computer-controlled transceiver and a multiband antenna system. In this example, the station is using a multiband trap dipole antenna. Note that a separate interface is needed between the computer and transceiver for frequency control.**

station transmits a "handshake" signal to the New York City station to confirm that a link has been established. All scanning stops and the ALE software sounds an alarm to call the operators to their stations.

ALE is a good tool for HF net operation in both routine and emergency applications where many stations may be standing by for calls. Think of ALE as being analogous to a VHF FM scanning transceiver with a digitally coded squelch that automatically scans several repeaters. Unless it hears the correct code, the radio remains silent. With amateur ALE you can call individual stations or entire groups of stations.

In addition to its application as a selective calling system for HF voice, ALE can also be used as a pure digital mode for exchanging text and images.

### AMATEUR ALE SOFTWARE

ALE has been used by the military and government for years, and hams have generally adopted the government ALE standards: FED-STD-1045 or MIL-STD 188-141. In 2001, ALE captured the attention of the amateur radio world with the release of *PCALE* software by Charles Brain, G4GOU. *PCALE* not only controls your transceiver, it uses your computer sound device to decode ALE signals and generate them for transmission. From the standpoint of assembling a station for ALE, it works best when two conditions are satisfied: 1) you have a multiband HF antenna system; the more bands the better; and 2) your HF transceiver can be controlled by computer.

Although you can use ALE on just one frequency, the real power of ALE comes into play when your station is able to operate on multiple bands under computer control. A typical setup is shown in **Figure 18** and includes a radio control interface as well as a sound device interface. With *PCALE* controlling your radio, it will automatically change frequencies, monitoring as many bands and frequencies as you have programmed into the software. For the latest on *PCALE* and ALE for amateur radio, do an internet search. Note that all ALE transmissions use USB. ALE must be used in accordance with the rules for stations operating automatic control.

# 7 D-STAR

The D-STAR digital protocol began in 2001 as a project funded by the Japanese Ministry of Posts and Telecommunications to investigate digital technologies for amateur radio. The research committee included representatives of the Japanese amateur radio manufacturers and the Japan Amateur Radio League (JARL). JARL is the publisher of the D-STAR protocol.

All radio manufacturers are free to develop D-STAR equipment, but at the time of this writing Icom and Kenwood are the only companies that have done so for the US amateur market. Neither company "owns" the original D-STAR protocol.

## 7.1 What is D-STAR?

The primary application of D-STAR is digital voice, but the system can handle any sort of data — including text, voice or images.

As shown in **Figure 19**, a D-STAR network

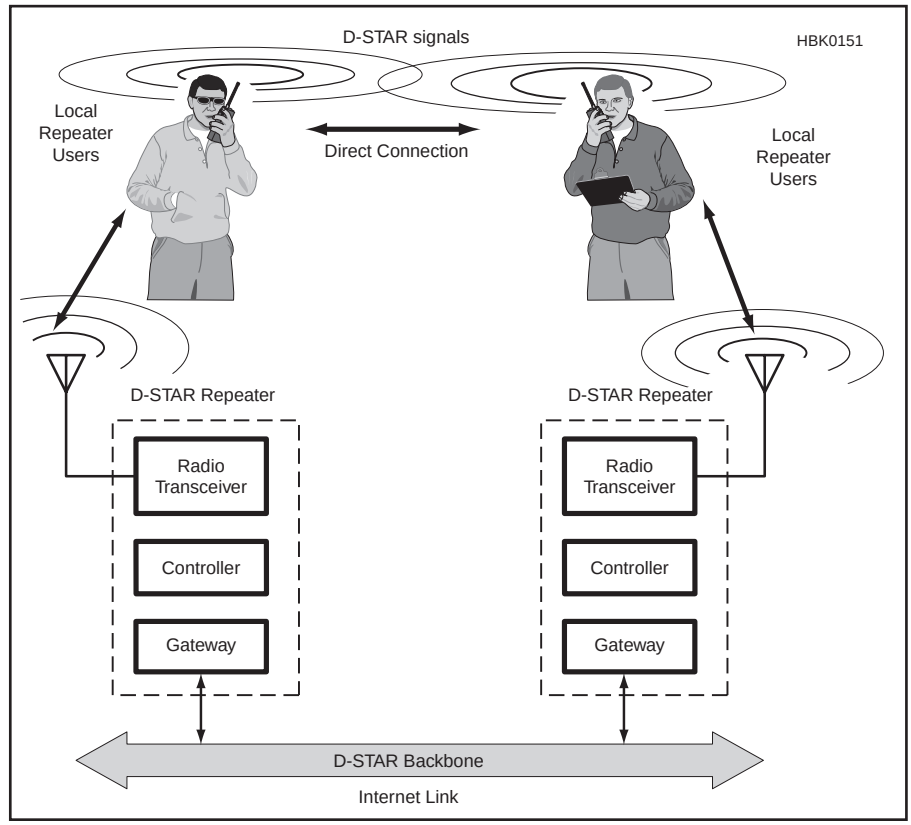

**Figure 19 — A D-STAR network can take several forms. D-STAR compatible transceivers can communicate directly (simplex) or through a D-STAR repeater for wide coverage.**

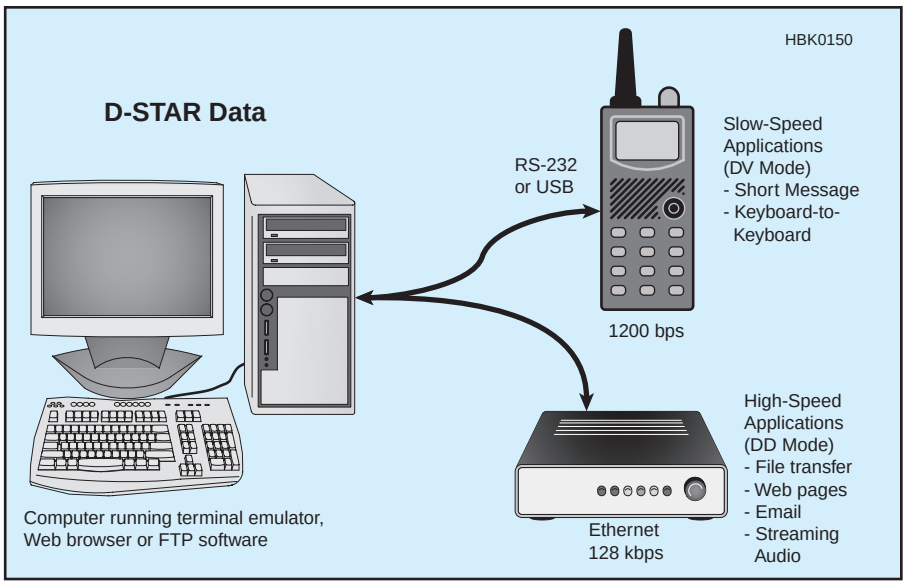

**Figure 20 — Radios that support DV voice and data present an RS-232 or USB 2.0 interface to the user.**

can take several forms. D-STAR compatible transceivers can communicate directly (simplex), or through a D-STAR repeater for wide coverage. D-STAR signals cannot be repeated through traditional analog repeaters without modification.

The D-STAR system carries digitized voice and digital data, but does the job in two different ways. There is a combined voice-and-data mode (DV) and a high-speed data-only stream (DD). From the perspective of the D-STAR user, data and voice are carried at different rates and managed in different ways, but over the air they are transported as bit streams.

## 7.2 Digital Voice and Low-Speed Data (DV)

The D-STAR codec digitizes analog voice by using the AMBE 2020 codec. AMBE stands for Advanced Multiple Band Encoding and 2020 designates the variation used by D-STAR.

AMBE can digitize voice at several different rates. The D-STAR system uses a 2.4 kbit/s rate that offers a good compromise between intelligibility and the speed at which data must be transmitted via the radio link. In addition, AMBE adds information to the voice data that allows the receiving codec to correct errors introduced during transmission. The net result is that the digitized voice stream carries data at a rate of 3.6 kbit/s.

Interleaved with the digitized voice information, D-STAR's DV mode also carries 8-bit digital data at 1200 bit/s. This data is used for synchronization in the D-STAR protocol with the remaining bandwidth available for use by the radio manufacturer. Icom uses the remaining bandwidth to carry repeats of the D-STAR RF header, the 20-character front-panel message, and serial data as described below.

Radios that support DV voice and data provide an RS-232 or USB 2.0 interface to the user as shown in **Figure 20**. (The RS-232 interface is restricted to RxD, TxD and ground — "three-wire" connection.) Any computer terminal or program that can exchange data over those types of interfaces can use D-STAR's DV mode capabilities as a "radio cable."

Because D-STAR's DV mode handles the data stream in an unmodified "raw" format, it is up to the equipment or programs that are exchanging data to manage its flow.

## 7.3 High-Speed Data (DD)

D-STAR's high-speed data mode is called *D-STAR DD*. This mode does not digitize the analog voice signal. The data-only packets sent over the RF link at a raw data rate of 128 kbit/s half-duplex, but since that includes the packet header and the delay between packets, the *net data rate* is somewhat lower. As with the DV mode, data is transmitted without modification, so flow control is left to the applications on each end. Radios supporting DD mode communications may also support DV mode.

Users connect to a radio supporting DD mode with an Ethernet interface via the usual RJ-45 modular jack found on computer networking equipment. The DD mode interface looks to computer equipment just like a customary IP network connection. Specifically, the DD mode interface is an Ethernet "bridge." This allows web browsers and other internet software to run normally, as if they were connected to standard computer network.

The net data rate of DD mode is comparable to or better than a high-speed dial-up internet connection. Any streaming media mode that will run over dial-up internet will likely perform well over D-STAR.

With its high signaling rate and 130-kHz bandwidth, FCC regulations restrict D-STAR DD operating to the 902 MHz and higher bands.

## 7.4 D-STAR Radios

At the present time, Kenwood offers a single D-STAR-compatible handheld transceiver, the model TH-D74A, for 2 meters and 70 centimeters.

Icom D-STAR radios are available in several models as mobile/base transceivers and as handheld transceivers. Except for the ID-1 base/mobile transceiver, which operates at 1.2 GHz, Icom D-STAR transceivers are designed to operate at 2 m, 70 cm or both. Icom D-STAR transceivers also support both digital and analog operation, which means that they can also be used for traditional analog FM communication as needed. An example is shown in **Figure 21**.

To determine the most appropriate D-STAR radio for an application, the first step is to understand the requirements:

- Is DD mode operation required (high-speed data)? If so, the only radio supporting DD mode is the ID-1.
- What bands are required? That will depend on activity in your area. If data is to be transmitted while in motion, higher frequencies will result in fewer transmission errors, improving the net data exchange rate. (Note: DD operation is only permitted on 902 MHz and higher.)

**Figure 21 — The Icom ID-51A is a 2 meter/70-cm handheld with D-STAR functionality.**

- Is high-power required? Using higher power base/mobile radios will result in stronger signal strengths and fewer data transmission errors.
- If data is to be transmitted, what data interface does the computer have?
- Error correction for low-speed data (DV mode) is the responsibility of the data communications programs used to exchange data. Make sure to carefully evaluate the software you intend to use.

More information about D-STAR may be found in the **Digital Protocols and Modes** and **Repeaters** chapters of the *ARRL Handbook*.

# 8 DMR: Digital Mobile Radio

Digital Mobile Radio (DMR) is not new technology as such, but what is relatively new is its adoption by the amateur radio community. DMR's origins are in commercial and public service applications such as police, fire, and so on. Amateurs began re-purposing 2 meter and 70-centimeter DMR transceivers by simply reprogramming them for ham frequencies and they did the same with commercial DMR repeaters. Many DMR repeaters are linked to the internet, creating a global network. The result has been substantial growth in DMR activity during the last several years. In addition, at the time of this writing, several manufacturers were marketing DMR transceivers to the amateur radio market in recognition of its increasing popularity.

More information about DMR may be found in the **Digital Modes and Protocols** and **Repeaters** chapters of the *ARRL Handbook*. A comprehensive introduction by W2XAB to the DMR protocol, operation using DMR, and the equipment needed for DMR is available at **www.raqi.ca/~ve2rae/dmr/Amateur_Radio_Guide_to_DMR.pdf**.

## 8.1 DMR Advantages

Digital Mobile Radio is spectrally efficient compared to other VHF/UHF digital modes. A DMR repeater can support two simultaneous digital conversations within a 12.5 kHz bandwidth. The repeater achieves this by using TDMA – Time Domain Multiple Access – to rapidly switch between data channels. A DMR repeater has two available time slots, which means that two individuals can effectively use the repeater at the same time and on the same frequency. The switching is so rapid that the signals are repeated seamlessly and with little interruption. If both timeslots happen to be in use, users hear a "busy" beep when they attempt to transmit.

Another advantage is a DMR repeater's ability to support analog FM transmissions in addition to digital. This factor has given an additional boost to DMR adoption.

## 8.2 DMR TalkGroups

A DMR repeater will typically offer several TalkGroups and these are simply "chat rooms" that cover a state or region. Thanks to internet linking, TalkGroups can also span the globe. Different DMR repeaters link to different TalkGroups, so it helps to obtain this information from the hams who use your local repeaters.

## 8.3 CodePlugs and Programming

Unlike an analog FM repeater that just requires the frequency pair and possibly a CTCSS tone, a DMR repeater requires the user's transceiver to transmit the call sign and "Color Code" of the desired repeater. DMR transceivers must be programmed with this information using a data file known as a CodePlug. Fortunately, CodePlugs and programming software are easily obtainable online, often free of charge. The best approach is to contact local DMR users for assistance. They'll know where to find CodePlugs not only for DMR repeaters in your area, but also throughout the region in which you reside.

# 9 System Fusion

System Fusion is a proprietary C4FM-based digital system developed by Yaesu. The use of the word "fusion" is a reference to the fact that Fusion hardware is capable of detecting analog or C4FM digital signals and automatically switching from one mode to the other as necessary, effectively "fusing" analog and digital functionality. The analog/digital detection and switching is completely transparent to the operator and does not require operator action of any kind.

Thanks to the automatic switching function, a System Fusion repeater can replace an existing analog FM repeater with little impact on analog FM users. A Fusion repeater will repeat all analog signals, regardless of the type of transceiver that generates them. In fact, FM users will not notice a difference except when the repeater is relaying a digital signal from a System Fusion transceiver. In that instance, analog users will hear a buzzing sound.

Unlike DMR or D-STAR transceivers, Yaesu System Fusion transceivers do not require elaborate programming beyond entering one's call sign when the transceiver is powered on for the first time. Using a Fusion transceiver with a Fusion repeater is as simple as squeezing the Push-To-Talk button. The "analog side" of a System Fusion repeater may require CTCSS tones in some instances and, of course, these would have to be programmed in the transceiver for analog FM use.

There are a variety of Yaesu System Fusion transceivers and their capabilities differ from model to model, but all can switch from analog to digital automatically. A basic Fusion radio supports digital and analog FM, but usually includes higher and lower quality digital voice modes. (The higher quality mode consumes somewhat more bandwidth and may be more vulnerable to "dropouts" under margin signal conditions.) More expensive transceivers add the ability to send and receive images, among other data. They also provide access to the global Yaesu WIRES-X network through repeaters that linked to the internet.

More information about System Fusion may be found in the **Digital Modes and Protocols** and **Repeaters** chapters of the *ARRL Handbook*.

# 10 HF Digital Voice

While D-STAR is the dominant digital voice/data system on the VHF+ bands, two very different systems can be found in operation on the HF bands. One uses dedicated hardware while the other two rely on sound devices and software. All require HF SSB transceivers, although they could just as easily be used on VHF SSB (or even FM) as well.

## 10.1 AOR and AMBE

The AOR Corporation was the first ham manufacturer to arrive on the scene with an HF digital voice and data "modem" in 2004. The fundamental design is based on a Vocoder protocol created by Charles Brain, G4GUO. His protocol involves the use of Advanced Multi-Band Excitation, better known as *AMBE*, a proprietary speech coding standard developed by Digital Voice Systems. Brain's protocol operates at 2400 bit/s, with Forward Error Correction added to effectively produce a 3600 bit/s data stream. This data stream is then transmitted on 36 carriers, spaced 62.5 Hz apart, at 2 bits/symbol, 50 symbols/s using QPSK. This gives the protocol a total RF bandwidth of approximately 2250 Hz (compared to 2700-3000 Hz for an analog single sideband transmission).

The AOR units, such as the ARD9800 (**Figure 22**), are designed to be as "plug and play" as possible. You simply plug your microphone into the front-panel jack and then plug the modem into the microphone input of your transceiver. A front panel switch selects digital encoding or analog transmission, so the unit can be kept in the line when not used for digital conversations. On the receive side, the modem automatically detects the sync signal of an AMBE transmission and switches to digital mode automatically. In addition to voice, the AOR modems can send digital data (typically images).

### AOR ON THE AIR

AOR digital voice is clear and quiet, an unusual thing to hear on an HF frequency. Tune around 14.236 MHz and you're likely to hear AOR AMBE signals. They sound like rough hissing noises.

During *QST* Product Review testing in 2004, the ARRL Lab discovered that decoding was solid down to about 10 dB S/N. Digital voice is an all-or-nothing proposition, however, and below that level the signals begin to break up. The result is absolute silence during those periods. Interference to the received signal produced a similar outcome.

The common approach on the air is to begin the conversation in analog SSB, then switch to digital. Each transmission starts with a one-second sync burst after the push-to-talk button is pressed. If the other station misses the sync signal, the audio doesn't decode and the transmission sounds like analog white noise. This means that for successful communication you must be on the correct frequency and ready to receive at the beginning of the transmission. However, if there is fading or interference during the sync transmission, you may be unable to decode the signal that follows.

A few additional steps will improve odds of success with AOR modems.

- Make sure that both stations are on the same frequency, within about 100 Hz.
- Set IF receive filters to 3 kHz or wider.
- Don't overdrive the modem audio input.
- Turn off transceiver speech compression.
- Don't overdrive the radio. If the ALC meter shows any activity, turn down the output from the modem.

Transceiver duty cycle will be substantially higher when you're operating digital voice compared to normal SSB. To avoid damaging your radio, it is a good idea to reduce your output by 25 to 50%.

## 10.2 FreeDV

FreeDV is an open-source software-based HF digital voice system for Windows, Linux, or OS X (**Figure 23**). It is designed to use a computer sound device or on-board sound chipset to send and receive amateur digital voice. Activity is primarily on HF at 14.236 MHz. In addition to the software, you need a

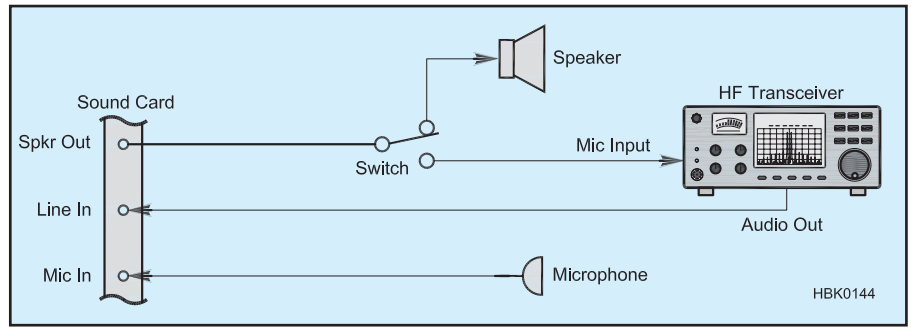

**Figure 24 — The single sound device approach to using *FreeDV* requires the means to switch the audio stream when switching from transmit to receive.**

**Figure 23 — *FreeDV* digital voice software. [N9SJA photo]**

**Figure 22 — The AOR ARD-9800 digital voice modem.**

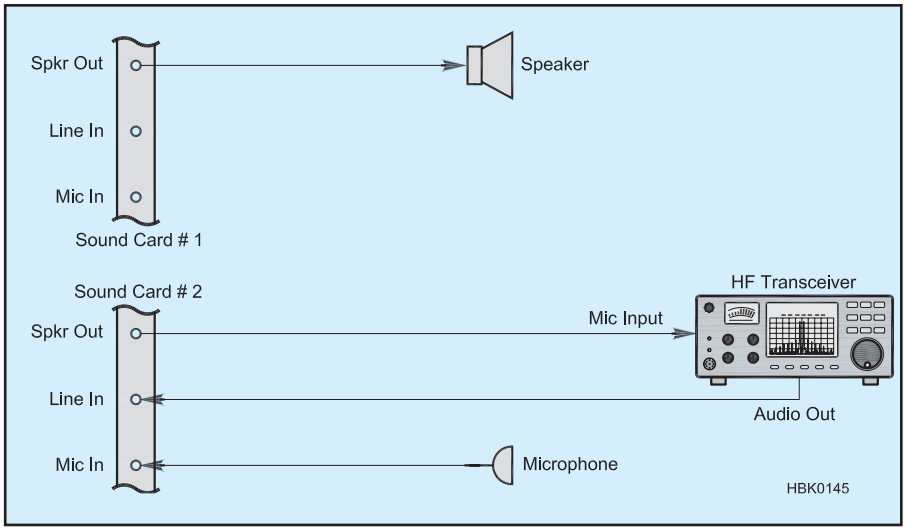

**Figure 25 — The most elegant, easy-to-operate solution for *FreeDV* is to use two sound devices — one to process the received signal and the other to generate the transmit signal.**

radio, computer and one of the sound-device interfaces discussed earlier in this article. Start by downloading and installing the *FreeDV* software at **freedv.org**. On this same website you will find documentation that explains installation and operation.

To receive, all you need is a cable between the audio output of your radio and the LINE INPUT of your sound device. You may need to get into your sound device control software and boost the LINE INPUT gain. If the signal in the waterfall display is too bright, reduce the gain control.

Transmitting with *FreeDV* is somewhat more complicated in terms of your station setup, especially if you have only one sound device. (**Figure 24**) The audio output from your sound device must be applied to your headset or PC speakers for receiving, but the *same* output must also feed your transceiver for transmitting, so a switch for the audio output is needed. The easier, more elegant approach is to use two separate sound devices. (**Figure 25**) The second sound device doesn't need to be high-end; you can use an inexpensive USB sound device for this application.

An alternative to the software and computer approach is available with the Rowetel SM1000 FreeDV adapter. The SM1000 integrates the entire FreeDV system within a handheld enclosure, allowing you to enjoy digital voice without a computer. At the time of this writing, the SM1000 was available for $201 US. See **www.rowetel.com** for more information.

# 11 EchoLink, IRLP and WIRES-X

Worldwide communication on HF requires reliable propagation and more substantial radio and antenna requirements than a basic VHF FM setup. By using internet links instead of HF radio links, a ham with a modest radio (even a handheld transceiver) can reliably communicate with stations hundreds or even thousands of miles away at any time of the day or night (**Figure 26**).

The most common form of amateur internet linking involves the exchange of audio using *VoIP* — Voice over Internet Protocol — technology. This is the same technology used by internet telephone services, and by online voice "chat" applications such as *Skype*, *TeamSpeak* and others. Three versions of amateur radio voice linking have become popular in the US: EchoLink, IRLP and WIRES-X.

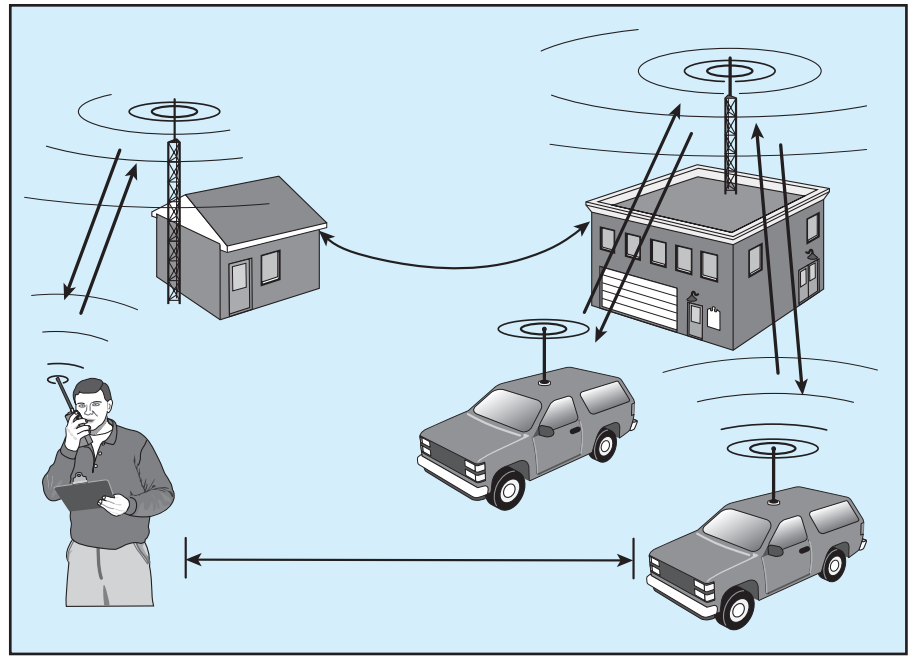

**Figure 26 — The internet VoIP link allows repeater users to speak with other amateurs who may be transmitting through other repeaters.**

## 11.1 EchoLink

EchoLink software, developed by Jonathan Taylor, K1RFD, is designed for Windows PCs, but there is a Mac version as well. With the software installed on a sound-device-

equipped computer, any ham can create an EchoLink *node* that others can access by radio. Hams can also join the network directly without using radios. They simply plug microphone/headsets into their computers.

Each EchoLink node is assigned a number that can be up to six digits in length. RF users access the EchoLink network by first sending the DTMF code required to activate the link on a repeater or simplex node. (**Figure 27**) Of course, this requires a transceiver equipped with a DTMF keypad. Once the link is up, they use the keypad again to transmit the number of the EchoLink repeater, link or user they wish to contact.

Hams who access the network directly (without a radio) select the person or system they wish to contact by simply clicking on its name in the software listing (**Figure 28**). The EchoLink network maintains continuously updated databases on several servers that indicate node and user locations and operational status. The network servers also support *conferencing* where many users can "meet" and speak together, either by direct access or via radio.

EchoLink supports communication among three different source groups:

• *Repeaters*: This is typically a VHF/UHF FM repeater with a computer at the site and a VoIP connection to the internet via EchoLink. When the EchoLink function is switched on, audio from the repeater is available on the EchoLink network, and vice versa. The internet VoIP link allows repeater users to speak with other amateurs who may be transmitting through other repeaters, or who may be linking directly.

• *Links*: Similar to repeater nodes, but operating on simplex frequencies without full repeater functionality. These are typically FM transceivers connected to computers. Depending on the station setup, their coverage can be confined to a neighborhood, or it may encompass an entire county.

• *Users*: This is strictly a computer-to-computer VoIP connection with no RF involved. In other words, the operator is sitting in front of his computer wearing a microphone/headset.

All the interfacing on the "RF side" of EchoLink is handled by connections to the computer sound device and serial port with a sound-device interface used to switch the radio between transmit and receive — the same setup used by sound device based digital communications such as PSK

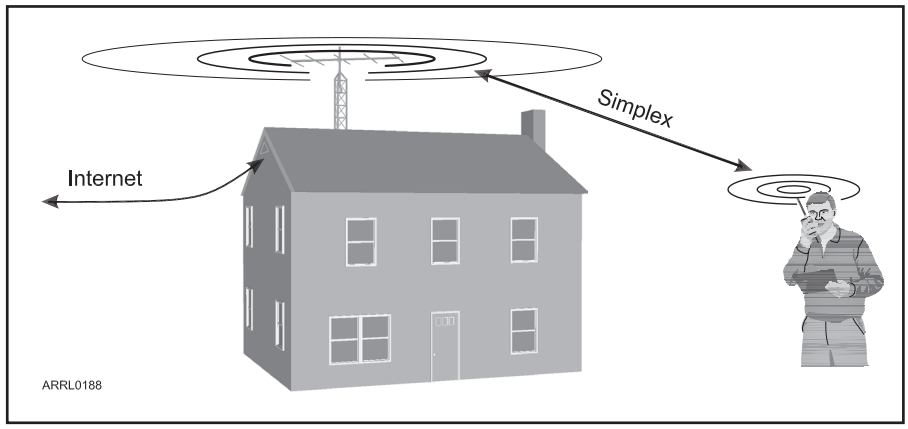

**Figure 27 — A typical EchoLink simplex node.**

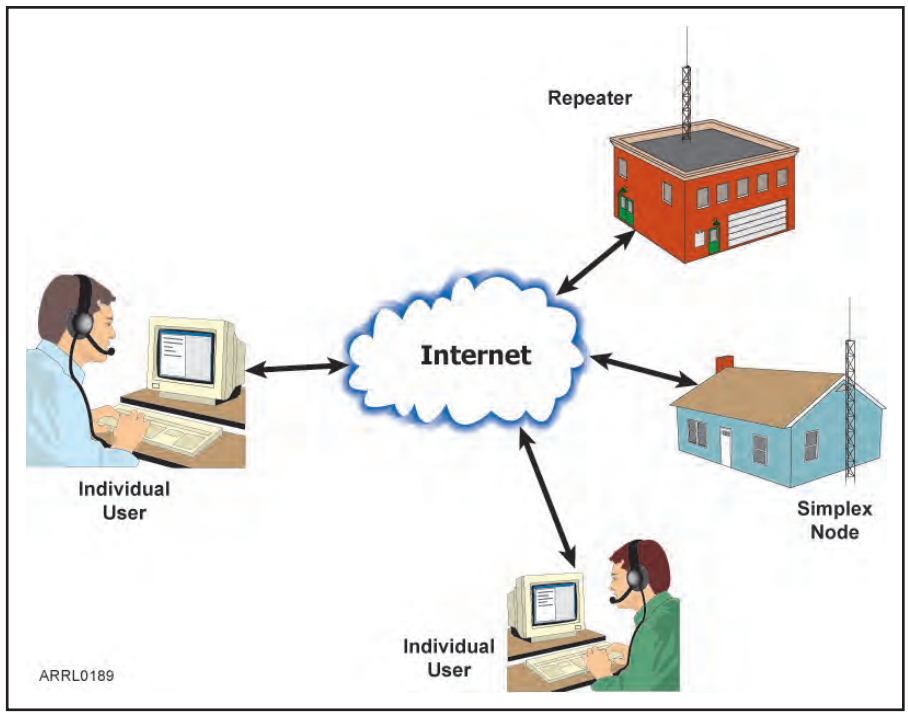

**Figure 28 — For some EchoLink users, there is no radio involved (at least at their end of the conversation).**

## ECHOLINK SECURITY

Before being granted access, every ham who establishes an EchoLink node, or who connects to the network directly, must provide positive proof of identity and license during the EchoLink registration process. After having been validated, each EchoLink node or user must provide a password, along with his or her call sign, to log in. Each time a connection is made for a QSO, the EchoLink servers verify both the sender and the receiver before communication can begin. Hams who use their radios to connect to the EchoLink network through a repeater or a simplex node do *not* have to be validated or provide a password. This is only necessary for the repeater or link stations, or for those who connect directly.

It is possible to configure EchoLink to accept connections only from certain types of stations: repeaters, links, users or all three. You can also set up a list of any number of "banned" call signs, which will not be allowed access. In addition, you can block or accept connections according to their international call sign prefix, to comply with reciprocal control-operator privileges or third-party traffic restrictions.

In Sysop mode, by default, EchoLink announces each station by call sign when the station connects. (The user can program a voice or CW ID that is generated automatically when needed.) The EchoLink software automatically generates detailed logs and (optionally) digital recordings of all activity on the link.

Unlike software such as e-mail programs, file-sharing programs and web browsers, EchoLink does not have any way to pass files or "attachments" that might harm your computer. There are no known cases of EchoLink

accepting or spreading a computer virus. Of course, any PC connected to the internet should always be protected by some sort of internet security hardware or software.

### 11.2 IRLP

*IRLP* stands for Internet Radio Linking Project. Like EchoLink, IRLP uses the internet to establish VoIP links. The difference is that IRLP only permits access via RF nodes at repeaters or on simplex frequencies (all IRLP nodes are interlinked via a central internet server). You must use a radio to access the IRLP network.

A typical IRLP node consists of a transceiver that is connected to the internet through dedicated IRLP hardware and software. This requires a Linux computer running IRLP software and an IRLP interface board, or a turnkey "embedded" IRLP unit that combines the Linux computer, IRLP software and interface in a single package. The IRLP software controls the VoIP audio stream using carrier operated squelch (COS) or continuous tone coded subaudible squelch signals (CTCSS) from the transceiver. When COS is present, the computer detects it through the IRLP interface board.

The operator connects to the IRLP network (at a repeater, for instance) using DTMF signals sent over the radio. As with EchoLink, this means that the operator must have a radio with a DTMF keypad. The actual access code is determined by the owner of the node. The user sends the correct DTMF sequence to bring up the IRLP connection, then sends the sequence of the distant node he wishes to contact. That might be a repeater in another state or a distant simplex node. You can view a list of current IRLP nodes at **status.irlp.net/**.

Here is an example of a typical IRLP connection:

- Press the transceiver PTT and identify your station. For example, "This is WB8IMY, Steve in Wallingford, Connecticut, USA connecting to node 8880."
- Next, press *#8880* (node 8880 in this example) on the DTMF keypad, release PTT and wait for the node connect announcement. The announcement indicates that your audio is now reaching the distant node. You can call a specific person, or just ask if anyone is around to chat.
- When finished, key PTT, make an announcement such as "WB8IMY releasing node 8880" and then press *#73* on the DTMF keypad to disconnect. The IRLP node will announce the disconnect and the node may now connect to a different node, reflector, or it will stand by awaiting another user.

It is interesting to note that there is a project underway (known as *EchoIRLP*) to bridge the IRLP and EchoLink networks.

### 11.3 WIRES-X

*WIRES-X* — Wide-Coverage Internet Repeater Enhancement System — is a VoIP network created by Vertex Standard (Yaesu). It is functionally like IRLP (including management via a central internet server), but nodes and repeaters are connected via a Vertex Standard HRI-100 interface and a computer running under the Windows operating system. Vertex Standard transceivers are *not* required for WIRES-X communication, but as with IRLP, all access must be via RF. WIRES-X also supports the Yaesu System Fusion network of repeaters for automatic routing and many other features.

There are two WIRES-X operational configurations using home stations (simplex nodes), repeaters or a combination of the two:

*SRG — Sister Radio Group*. You operate within WIRES-X in a small (10 node maximum) network that is ideal for closed-group operations. Within the network, all nodes operate using the same repeater node list, so you can link only to stations within this 10-node network. Because there are only ten nodes maximum, access to any of these nodes is possible using a single DTMF tone when calling. At the beginning of each transmission, this single DTMF tone locks communication between the calling node and the called node, but local (non-linked) transmissions are also possible, simply by omitting the DTMF tone at the beginning of the transmission.

*FRG — Friends Radio Group*. You may call any repeater registered with the WIRES-X FRG server. In the case of FRG operation, a six-digit DTMF code is required for access, and once the link is established this code need not be sent again (this is called the LOCK mode), unless the operator wants the ability to make non-linked transmissions (UNLOCK mode), in which case the six-digit code must be sent at the beginning of each transmission (using the DTMF Autodial feature of the transceiver, for example). Group calling to preset 10-repeater B, C, and D lists is also possible.

SRG is similar in philosophy to the local FM voice repeater where you tend to talk to the same group on a regular basis. FRG is similar in concept to IRLP, linking together a worldwide group of repeaters and base stations.

## 12 FT8 and FT4

When you hear someone referring to the "WSJT modes," they are talking about the digital operating modes included in the *WSJT* software suite created by Dr. Joe Taylor, K1JT. *WSJT* — now known as *WSJT-X* and supported by a team of protocol designers and programmers — offers several different modes, each with its own strengths for a given application.

*WSJT* had its beginnings as a collection of software for moonbounce communication. As a Nobel Prize-winning scientist who studies pulsars and other distant astronomical objects, Joe has a keen interest in weak signals, the kind hams encounter when reflecting signals from the lunar surface. Joe's software exploits the power of modern desktop and laptop computers to separate weak signals from noise and decode the information they contain. With just a sound card or sound chipset and a transceiver interface, *WSJT* made it possible for hams with modest stations to enjoy VHF meteor scatter communication and even moonbounce. Prior to Joe's invention, hams needed to make large investments in antennas, transceivers, and amplifiers to pursue these activities. The advent of *WSJT* opened an exciting world of operating for many who could not otherwise afford it.

But it wasn't long before someone wondered what would happen if one of the *WSJT* modes, known as JT65, was used on the HF bands. Digital communication on HF isn't nearly as challenging as getting a signal to the moon and back, so it stood to reason that there would be plenty of "performance margin" to provide fascinating results. To no one's surprise, this turned out to be true. Using a variant of JT65 known as JT65A, even a few watts of JT65-modulated RF to a wire dipole antenna resulted in transcontinental and even global communication.

JT65 became a popular HF digital operating mode in short order and, by 2016, it even eclipsed PSK31. Then, in 2017, a version of *WSJT-X* was released that included a new mode: FT8.

FT8 took off like a proverbial rocket. It offered many of the benefits of JT65 but was a much faster and somewhat semiautomated mode. By the end of 2017, FT8 had become the most widely used digital mode on the HF bands.

Like its cousin, JT65, FT8 is not a "conversational" mode. In fact, there isn't a conversation taking place at all. Instead, all you are doing is making contact and exchanging call

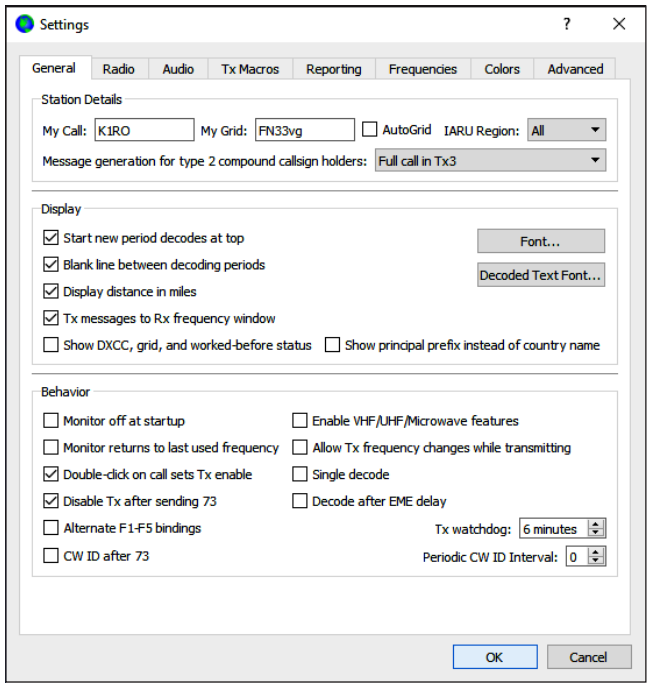

**Figure 29 — The *WSJT-X* settings screen. The tabs along the top allow you to set up your operating preferences, customize the screen appearance, and interface the software with your transceiver.**

signs, signal reports, and grid square locations with acknowledgements when the information is received. So, what is the attraction of modes like FT8?

- They provide "honest," objective signal reports. The software automatically makes a signal-to-noise (SNR) measurement and generates a report for the other operator. Signal strength is expressed in dB (decibels). For example, a –25 dB signal is quite weak while a +4 dB signal is very strong. These reports give you a true sense of how well your signal is being received. This is critical when testing antennas or studying propagation.
- The performance of FT8 is such that even a minimal station, such as someone transmitting 5 W to an attic antenna, can make large numbers of contacts, including contacts with stations in other countries.
- Their exchanges provide all the information needed for valid contacts that can be applied to awards such as the ARRL DX Century Club (DXCC).

And for FT8, another attraction is speed. It is possible to complete an FT8 contact in little more than 90 seconds.

## 12.1 Getting Started with FT8

To get started with FT8, you must first download and install *WSJT-X*. While most hams use the Microsoft Windows operating system, you will also find versions of *WSJT-X* for macOS and Linux at **physics.princeton.edu/pulsar/k1jt/wsjtx.html**. Be sure to use Version 2.0 or higher —earlier 1.x versions are not compatible with the new version, and you won't be able to work anyone.

When you start *WSJT-X*, you'll see two windows: a main window with menus for the settings, options, and the information being decoded, and a separate window for a combined waterfall and spectrum display. Each window can be moved on your monitor and resized to suit your preference and the monitor's resolution. More on these two windows later.

First, before you can use *WSJT-X*, you need to set up the software. At the upper left, click on the **FILE** menu option and choose **SETTINGS** (or just press the F2 keyboard shortcut) to bring up the screen shown in **Figure 29**.

In the **STATION DETAILS** section, you will need to enter **MY CALL:** and **MY GRID:** for your station. If you don't know your grid square, Dave Levine, K2DSL, has a handy calculator at **www.levinecentral.com/ham/grid_square.php**.

Under **DISPLAY**, check the first two options to help make it easier to follow decoded text when you are on the air. Check the third box to show distance in miles (unchecked for kilometers). Check the fourth box to show your transmitted messages in the receive frequency window. (That way, when you are in a QSO, you can see alternating lines showing what you sent and received. More on this later.) An important feature in the **DISPLAY** section is the **FONT** and **DECODED TEXT FONT** buttons, which you can click on to match the size and type of the font you prefer.

Under **BEHAVIOR** check the third and fourth options. Check **DOUBLE CLICK ON CALL SETS TX ENABLE** so you do not have to constantly hit the **ENABLE TX** button whenever you want to transmit. The instructions in the rest of this section will be written under the assumption that you've checked the **DOUBLE CLICK ON CALL SETS TX ENABLE** box. Also check **DISABLE TX AFTER SENDING 73**, which is a safety valve of sorts, preventing your continual transmissions even after your contact has completed with a 73 message. You can read about the other options in *WSJT-X* documentation, but these are the most important ones.

Under the **RADIO** tab, you can pick the method of switching your radio to the transmit mode. You'll find it in the **PTT METHOD** box. If you pick **CAT** control, you must choose the correct communication protocol for your transceiver (by using the drop-down **RIG** menu at the top), the serial (COM) port number, the COM port data rate, and the parity values for your rig in the **CAT CONTROL** box at the immediate left. Note that if you activate CAT without your radio turned on, or if *WSJT-X* is unable to communicate with your radio because of an incorrect COM port or speed setting, the program will generate an error message and you won't be able to continue.

Choose VOX (voice operated switch) in the **PTT METHOD** box if you are using an interface with VOX switching that responds to audio from your computer, or if you intend to allow your transceiver to switch from receive to transmit with its own VOX circuit.

Some transceivers will do transmit/receive switching (PTT) through the CAT connection. If your radio is one of these, select **CAT** as your PTT option. Otherwise, select either **RTS** or **DTR** and a COM port number for your keying device. In most cases this will be one of the interfaces we discussed earlier in this book. There is a **TEST PTT** button and **TEST CAT** button that you can use to be sure your PTT and/or CAT circuit is working.

CAT control is not necessary to operate *WSJT-X* in any mode, but it is awfully convenient. For example, when you use the drop-down menu in the main window to select your operating frequency, your transceiver will switch to that frequency automatically.

The next step is to select the **AUDIO** tab and choose the **SOUND CARD** device, both **INPUT** (receive) and **OUTPUT** (transmit). You may want to select **MONO** for receive audio and **BOTH** (left and right channels) for transmit. You can pick whatever works for your radio and computer, but be careful; some of the earlier Kenwood HF SSB radios, for example, have the left and right channel audio reversed on the USB pins, so you may have to pick **BOTH** for the output audio.

You also have the option to select your

LOGGING QSO choices and to report the stations you copy to the PSKReporter web page (**www.pskreporter.info/pskmap**). This is a valuable tool that keeps track of digital mode signals received on all bands, in a variety of modes. If you have an internet connection at your station computer, be sure to check the ENABLE PSKREPORTER SPOTTING box.

When you exit the setup mentions and return to the main window, pick FT8 in the MODE menu and pick the DECODE speed. Selecting FAST decode will work well for most computers. If you are blessed with a very fast machine, you can select NORMAL or DEEP, which will allow you to decode weaker signals. However, this takes more time and could delay the speed at which the results appear on your monitor.

## 12.2 Navigating the Windows

When you start *WSJT-X*, you'll see two windows: a main window with menus for the settings, options, and the information being decoded, and a separate window for the combined waterfall and spectrum display. Each window can be moved on your monitor and resized to suit your preference and the monitor's resolution.

### THE WATERFALL/SPECTRUM DISPLAY WINDOW

**Figure 30** shows the *WSJT-X* waterfall/spectrum window as recorded with the VFO set for 14.074 MHz (upper sideband). The top 80% of the display is a waterfall that shows received signals, while the bottom 20% is called the spectrum window and shows the strength of signals in the passband.

The numbers at the top of the waterfall represent the audio frequencies (pitch) from 200 Hz to 2500 Hz, with the receiver set for an SSB-width bandpass filter. (This is just a portion of the passband. It can be set to 3000 Hz or even wider depending on your transceiver filtering.) The vertical axis in the waterfall represents time in 15 second intervals. (FT8 contacts follow a carefully times sequence of 15 seconds transmitting, 15 seconds listening.)

The vertical axis in the spectrum window represents the signal strength (dB). There are options to adjust the waterfall speed, frequency span, start frequency, averaging pattern and other parameters, but you can leave these at their default settings for now.

The signal strength of each FT8 signal can be estimated by its peak amplitude relative to the average noise floor. In the waterfall, the strongest signals show up as a solid orange. Two FT8 signals will often overlap somewhat in frequency, but the software does an excellent job separating the individual messages.

### MAIN WINDOW OVERVIEW

**Figure 31** shows the activity in the afternoon on 20 meters (14.074 MHz) at K1RO. The BAND ACTIVITY window on the left shows stations copied. Note that the band was busy, with a mix of stations in North America, Europe, and Africa represented.

The gray bar with the 20m label signals the beginning of the most recent 15-second listening period. Below that are lines showing each station copied. From left to right, each line shows time in UTC (hour, minute, seconds — for example, 204300). Next is received signal strength (SNR in dB), and then DT, which is any difference (in seconds) in time between the station you are receiving and your own computer's clock. The FREQ column is the received station's audio frequency within the passband in Hz. The MESSAGE column shows what was sent in that sequence. In this case, it's a mix of CQs, stations calling other stations, and stations sending signal reports or confirmations to each other. Check the CQ ONLY box just below the window to show only received stations who are calling CQ.

The RX FREQUENCY window shows activity on or very near the frequency selected by your receive cursor. The top five lines show three transmissions from Z81D, and two transmissions from EA5BFA who is calling Z81D on that frequency. The last line, which is highlighted, is K1RO calling Z81D on a frequency higher in the passband. It shows up here because TX MESSAGES TO RX FREQUENCY WINDOW is checked in the SETTINGS.

Each line represents a 15 second time interval, and the line are color-coded to help keep track of what is happening. Color coding is adjustable in the settings. For example, in this case green represents another station calling CQ, yellow represents your transmissions, and red represents other stations' transmissions to you.

In the row of gray buttons below the BAND ACTIVITY and RX FREQUENCY windows, the *WSJT-X* MONITOR button must be engaged to receive and the ENABLE TX button must be engaged to transmit. HALT TX instantly stops transmission, and TUNE sends a solid carrier to check the transmitter and set power levels. DECODE forces a decode of the most recent time segment, ERASE clears one or both windows, and LOG QSO brings up a window

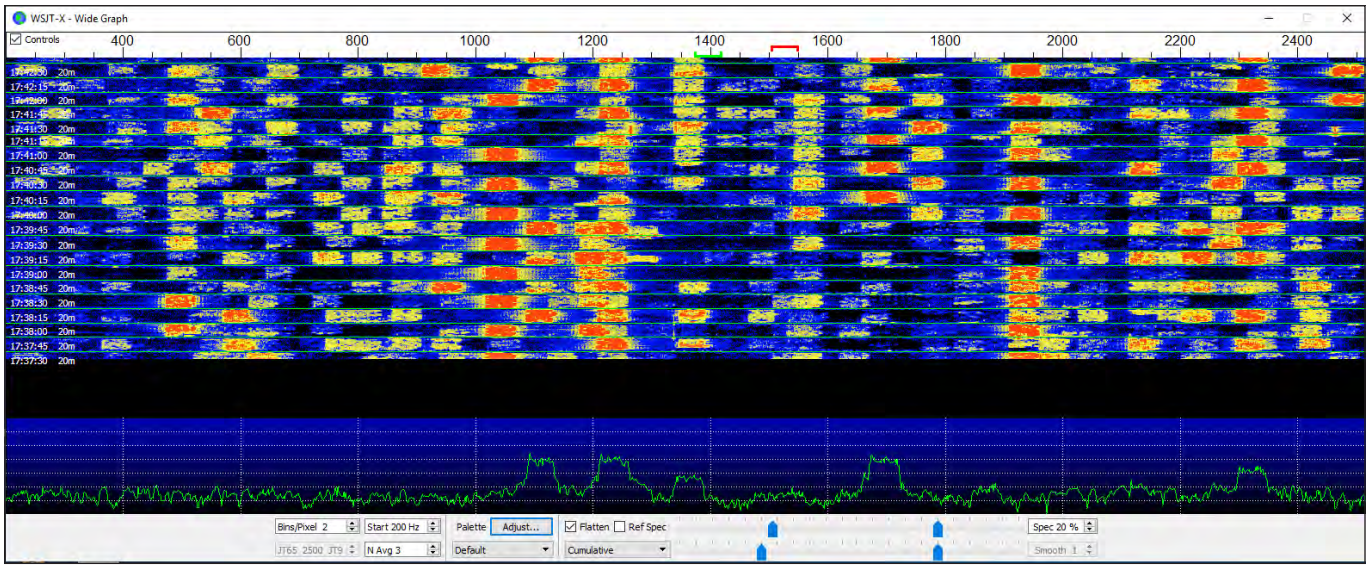

**Figure 30 — The *WSJT-X* waterfall/spectrum window as recorded with the VFO set for 14.074 MHz (upper sideband). The numbers above the waterfall represent the audio frequencies (pitch) from 200 Hz to 2500 Hz. The horizontal lines represent 15 second intervals. Each fuzzy "square" represents an FT8 transmission (the stronger the signal, the brighter the "square").**

to log the contact.

The messages that K1RO will send during a contact are shown in the **GENERATE STD MSGS** section in the lower right and are generated automatically. In this case, when K1RO clicked on a Z81D decode in the **BAND ACTIVITY** window, the software generated the messages shown. The messages can be sent manually by clicking on the button next to the desired one. If you check the **AUTO SEQ** box to the left, messages are sent automatically in the correct sequence once a contact is initiated and the correct response is received from the station you are working. We'll have more detail on making a contact later in this section.

To the far lower left in this window a vertical scale, 0 to 90, showing the total strength of *all* received audio signals (like an S-meter on your rig), which at this moment reads 50 dB. You don't want too much, or too little received audio. The **PWR** slider at the far right is for adjusting your transmit power.

Above the received signal indicator is a drop-down menu for selecting the band manually, and to the right of that is a window showing the radio's current VFO frequency if you have set up *WSJT-X* to read your transceiver's frequency directly. Having the correct frequency in this window is very important for logging contacts or if you send your data to online databases.

Below the frequency window is information about the station you are calling, and below that the current date and time. To the right of the date and time are options to set your transmit and receive audio frequencies within the passband and to change the signal report from the one generated automatically. There's also a checkbox to toggle your transmissions between the odd and even segments (for example, in a given minute, starting at 00 seconds is even, starting at 15 seconds is odd).

The checkbox for **HOLD TX FREQ** is just that — if you call someone, or someone calls you, your receive frequency moves to the spot where the other station is transmitting but your transmit frequency stays where it is. Check the **CALL 1ST** box, and if multiple stations are calling you, the software will automatically respond to the first one decoded.

Remember that the radio's VFO is left set to the FT8 operating "watering hole" frequency (in this example, 14.074 MHz). The radio's displayed carrier frequency is not changed or tuned.

## 12.3 The Importance of Time

In every *WSJT-X* operating mode, a critical component is time. The software depends on tight time synchronization to "know" when to expect data signals to be present so they can be decoded. Your computer clock doesn't need to match the clocks of other stations exactly, but it must be synced within less than 2 seconds – the closer the better. If your computer clock is too far out of sync, you will not be able to decode signals.

When you look at decoded signals, pay attention to the numbers in the DT column. If you notice that most of the numbers are greater than 1, that's a clue that your clock computer is drifting out of sync with the other stations.

Fortunately, Windows has built-in time calibration that synchronizes automatically with time sources via the Internet. In my experience, however, the synchronization doesn't take place as often as it should and, as a result, your PC's time may drift by a second or so after just a few days.

Fortunately, Windows has built-in time calibration that synchronizes automatically with time sources via the internet. In my experience, however, the synchronization doesn't take place as often as it should and, as a result, your PC's time may drift by a second or so after just a few days. My recommendation is to periodically "force" resynchronizing. In *Windows 10*, for example, open **Control Panel** and click on **TIME & LANGUAGE**. In the **Date & time** screen, you will see a section labeled **Synchronize Your Clock**. You can see when the time was last synchronized, and force synchronization by clicking on **Sync Now**. You don't necessarily need to do this before every operating session, but it doesn't hurt.

A more convenient alternative is the free time-synchronizing application *Dimension 4*, which you can download at **www.thinkman.com/dimension4/**. Install the application and set it up so that it loads and runs constantly in the background whenever you start your

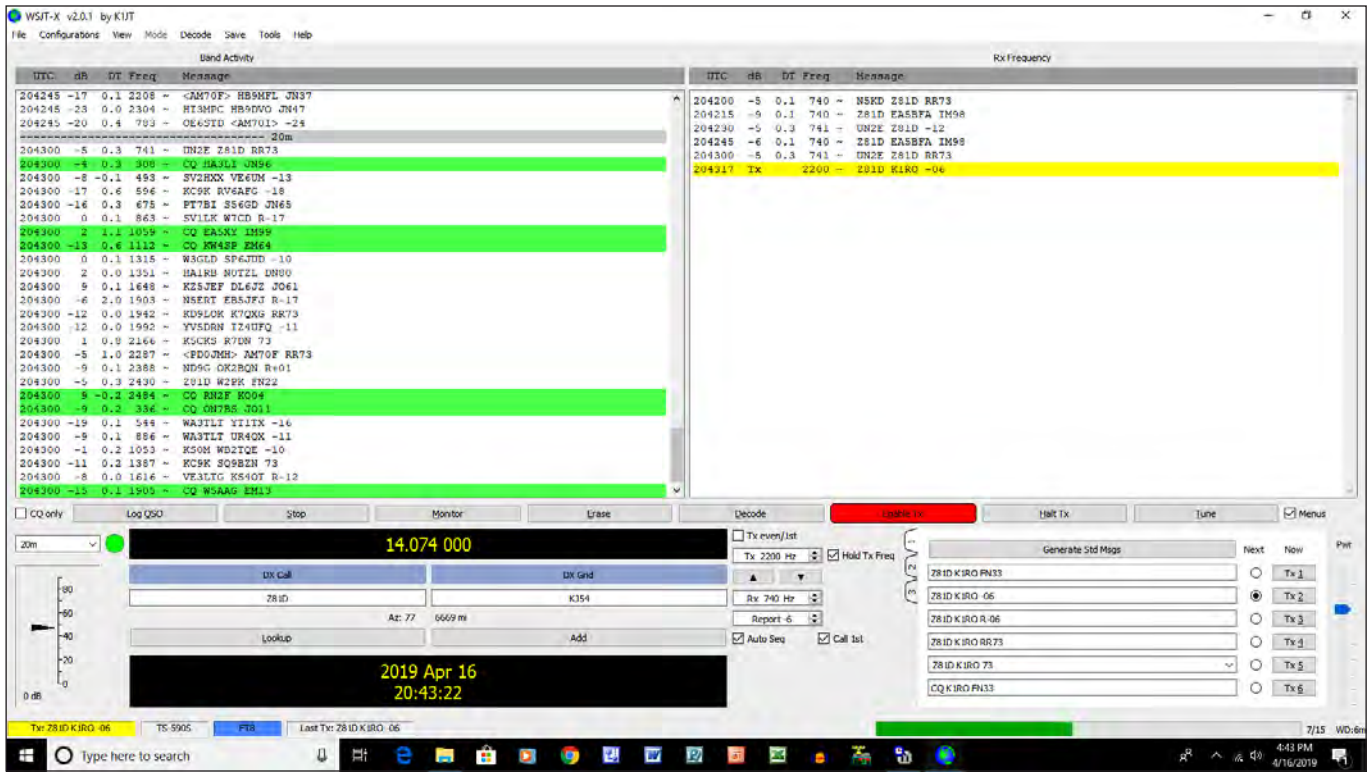

**Figure 31 — The *WSJT-X* main screen in the FT8 mode, decoding signals on 20 meters.**

computer. Another popular alternative is *Meinberg NTP* (**www.meinbergglobal.com/english/sw/ntp.htm)**

## 12.4 On the Air with FT8

With the menu items set and saved, the next thing to do is to pick a frequency and listen for activity. You can't miss the sweet slow sounds of FT8 tones once you hear them. They are a much shorter tone duration than the even slower JT65 tones, which are often present 2 kHz higher in the band.

Do *not* choose a narrow passband 500 Hz filter if your radio offers one. Keep your IF passband set for a normal phone conversation, 2 to 3 kHz. This will allow you to see every signal that is scattered throughout the receive passband.

Having said that, there are times when you may want to use a narrower bandwidth. For example, if there is a station in the passband that is extremely strong, that signal may cause your AGC to reduce your receiver gain dramatically, causing weaker signals to disappear. Switching in a filter may help block the strong signal.

Never use speech processing, and never turn on noise blankers, or noise-reduction software. They will distort your transmit signal and receive signals respectively. Also, if your transceiver has an AGC adjustment, set it to "fast."

Set your transceiver for maximum RF output (typically 100 W for many radios) and place it in the USB or USB-Data mode. Start by clicking your mouse on an empty area of the waterfall display. You'll notice that the red/green brackets above the waterfall will move to that position. Next, click on the **TUNE** button in the *WSJT-X* main window. If you've set up everything correctly, *WSJT-X* should key your transceiver and transmit a continuous tone.

Quickly click your mouse on the **PWR** slide control on the right side of the main window and drag it down. Watch your transceiver's RF power output and ALC metering. Keep dragging the **PWR** control down until you see no ALC indication, or until the ALC meter indicates that it is within the minimal zone.

Continue dragging the **PWR** control until your RF output drops to where you feel it should be. You definitely don't need 100 W, but how much is too much? Many FT8 enthusiasts say you should never transmit more than 30 W; others suggest even less. The answer really depends on your antenna system. If you are using a gain antenna such as a Yagi, 30 W or less would be appropriate. On the other hand, if you are using a poor antenna such as an HF mobile whip sitting in your back yard with a couple of radial wires in the grass, you may need more than 50 W to be effective. My recommendation is to start very low and see what sorts of signal reports you receive. If you consistently receive weak reports from most stations, that's a strong hint that you should probably increase power.

After tuning up, you are ready to operate, but before you make your first contact, start by just listening and observing. The first thing you'll notice is that transmissions take only 13 seconds, with a two-second pause between transmissions. This means the length of each transmit or receive cycle is a total of 15 seconds.

As you observe the exchanges, you'll probably see a pattern emerging. FT8 exchanges usually, though not always, follow a strict sequence. It goes like this, starting at 21:02:00 UTC. Note that when there is an exchange between two stations, the transmitting station's call sign is the one on the *right*.

21:02:00 — CQ WB8IMY FN31
WB8IMY sends CQ from grid square FN31.

21:02:15 — WB8IMY N1NAS EN72
N1NAS replies and tells WB8IMY that he is in grid square EN72.

21:02:30 — N1NAS WB8IMY -11
WB8IMY replies with a signal report of -11 dB.

21:02:45 — WB8IMY N1NAS R-15
N1NAS acknowledges the signal report from WB8IMY with an "R" followed by a signal report (-15).

21:03:00 — N1NAS WB8IMY RRR
WB8IMY sends "RRR," which means "Roger, roger, roger." Everything has been received and the exchange is complete.

21:03:15 — WB8IMY N1NAS 73
N1NAS sends 73 – best wishes.

21:03:30 — N1NAS WB8IMY 73
WB8IMY sends his 73 as well. The contact has ended.

The entire contact is complete within just 90 seconds, start to finish. Of course, this assumes that all goes well. If there is noise, fading, or interference that corrupts reception, an exchange may need to be repeated, and that will take longer. Under decent signal conditions, however, most contacts are completed in less than two minutes. **Figure 32** shows a contact between K1RO and K9IG, followed by K1RO working WVØI.

### MAKING CONTACT

If you're comfortable monitoring FT8, it is time to try a contact. Watch for someone calling CQ. Depending on how you've set up your colors in *WSJT-X*, a CQ may appear as green-shaded text. Make sure you've checked the auto sequence (**AUTO SEQ**) box.

Keep in mind that FT8 is a bit different from traditional CW or SSB operation. You can call another station anywhere in the audio passband, and split-frequency contacts (different transmit and receive audio frequencies) are very common. It's a good idea to set your transmit frequency to a clear spot and enable **HOLDTX FREQ** to keep your transmissions in that clear spot, rather than trying to call another station where they are transmitting.

When you see a CQ, quickly double-click your mouse on the text. *WSJT-X* should respond by keying your transceiver and sending the other station's call sign, your call sign, and your grid square. Now just sit back and watch; *WSJT-X* will handle the rest.

Automatic operating depends on *WSJT-X* receiving the correct text at the correct times. If it does, it will select the correct response

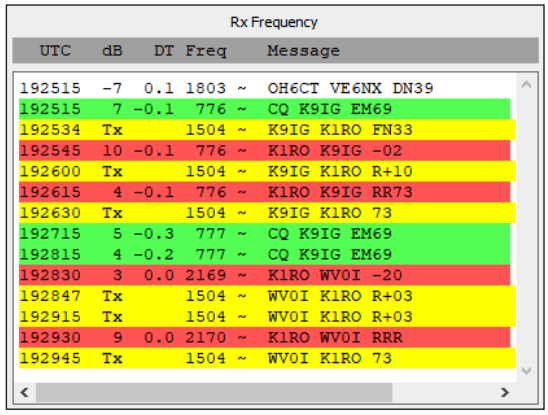

**Figure 32 — The *WSJT-X* Rx Frequency window showing activity at station K1RO in grid FN33. Starting with the second line: K9IG in grid EM69 calls CQ on 776 Hz. K1RO answers, transmitting on 1504 Hz. K9IG sends K1RO a –02 dB report. K1RO responds with an R (roger) and sends a +10 dB report. K9IG acknowledges that and sends 73 (RR73). K1RO sends the final 73. K9IG calls CQ twice more. Note that K1RO transmitted on a clear frequency, 1504 Hz, rather than switching to K9IG's CQ frequency.**

**Next, K1RO's receive frequency jumps to 2169 Hz because WVØI has called there and sent a –20 dB report. K1RO, still transmitting on 1504 Hz, acknowledges and sends a +03 report (R+03). K1RO did not hear a response from WVØI and so repeated that transmission. This time, a RRR acknowledgement report is received from WVØI, so K1RO sends 73 to complete the contact.**

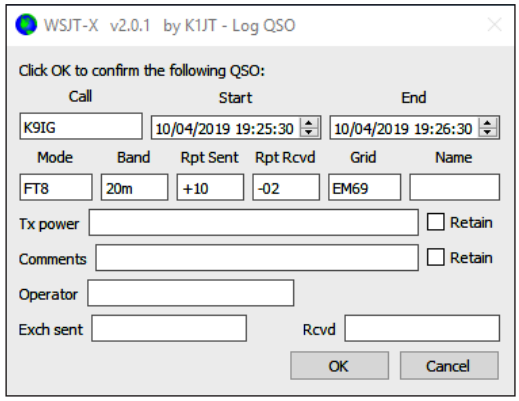

**Figure 33 — When K1RO completed the contact with K9IG (ie, reports were sent in both directions and acknowledgements received), the *WSJT-X* logging window popped up to record the contact. *WSJT-X* stores the contact information in both text and ADIF format for transfer to other logging software or online databases such as ARRL's Logbook of the World.**

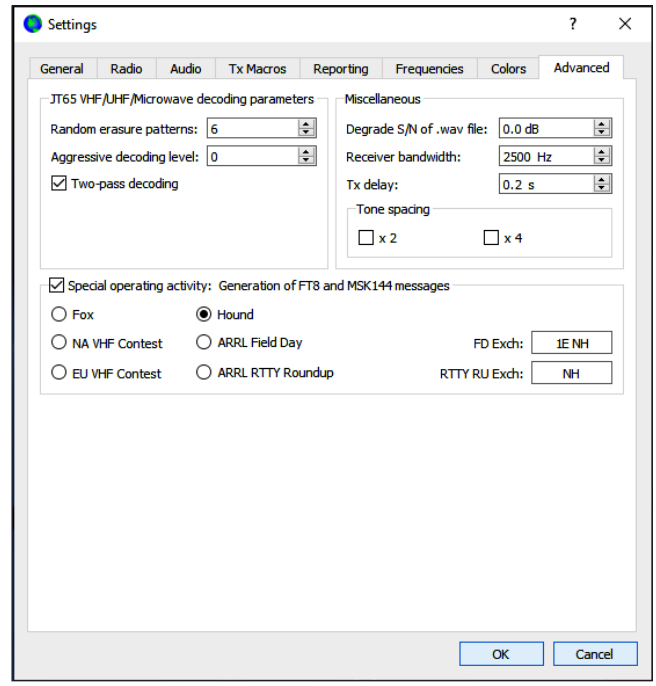

**Figure 34 — The Advanced tab in the *WSJT-X* Settings menu is used to set up special operating activities such as Fox/Hound DXpedition mode, ARRL Field Day, or contests such as ARRL RTTY Roundup.**

and send it automatically. You won't need to lift a finger. When the station responds to you, *WSJT-X* should respond in turn.

Sometimes, however, things do not go as planned. The station may send a signal report, but will not receive your confirmation and your report. Perhaps there was interference, or maybe conditions suddenly changed. If so, you may see the station repeating its report of your signal, and *WSJT-X* responding by sending your report of the other station's signal again. The other station's *WSJT-X* is doing this automatically because it didn't decode your text the first time around. Just wait as *WSJT-X* tries again. With luck, the station will receive and decode properly on the next attempt.

Once the contact is complete, usually with a 73 message, you'll notice that the **ENABLE TX** button is no longer highlighted. You may also receive a prompt to add the contact to your *WSJT-X* log, if you've enabled that prompt in the settings menus (see **Figure 33**).

### TRY CALLING CQ

After you've made a few contacts, try calling CQ yourself. Once again, check the **AUTO SEQ** box, but this time you need to also check the **CALL 1ST** box to its immediate right. The **CALL 1ST** box is important because it lets *WSJT-X* know that you want to respond automatically to the first decoded responder to your CQ. If you don't check that box, you will need to double-click on the text line from a responding station to start the contact sequence.

Pick a point in the waterfall window where no one seems to be transmitting. Double-click your mouse on that point and the red/green brackets will jump to that position.

Now look in the **GENERATE STD MSGS** window and click your mouse in the circle on the bottom line, just to the left of the **TX 6** button, which should be your CQ message. Click the **ENABLE TX** button and *WSJT-X* should begin transmitting. If you happen to begin at the middle or near the end of a transmit cycle, the first transmission may be short. *WSJT-X* will likely wait until the *next* cycle is complete before sending the CQ transmission again.

During receive cycles *WSJT-X* will be "watching" for text that contains your call sign, the call sign of another station, and a grid square — in other words, a reply! If no one replies, *WSJT-X* will send CQ again. When someone does reply, it will automatically go through the "dance" of completing the contact while you relax and watch.

### ADDED FEATURES

*WSJT-X* software is constantly evolving, and it is nearly impossible to provide up-to-date information within the pages of a printed book. For instance, in the **ADVANCED** tab in **SETTINGS** (see **Figure 34**), later versions of *WSJT-X* added the "Fox/Hound" configuration to handle DX pileups. The DX station — the so-called "fox" — transmits low in the passband, and those in pursuit of contacts — the "hounds" — are spread among other frequencies above 1000 Hz. The fox can respond to multiple stations simultaneously, greatly increasing the contact rate. Fox/hound operations generally occur on frequencies outside the normal FT8 watering holes.

There is also a configuration specific to contest applications, one that allows sending the correct exchange for the event. Currently, VHF contests (grid squares), ARRL RTTY Roundup (RST and state), and ARRL Field Day (entry class and ARRL section) are supported as well as contests sponsored by other organizations that use one of these exchange formats. *WSJT-X* can communicate with some contest logging/station management software such as *N1MM+ Logger*.

## 12.5 FT4

*WSJT-X* Version 2.1 debuted with a new mode designed specifically for contesting: FT4 (see **Figure 35**). Compared with FT8 it is 3.5 dB less sensitive and requires 1.6 times the bandwidth, but it offers the potential for twice the QSO rate. Once you've set up *WSJT-X* as described in this section, you will be ready to try FT4. The exchanges are very much the same as FT8, only much faster. FT4 also supports the text exchanges required according to the rules of various contests.

At the time of this writing, FT4 was in use alongside FT8 for contest applications. Contests such as ARRL RTTY Roundup offer categories for FT8/FT4 operation as well as conventional RTTY. The Worldwide Digi DX Contest and FT Roundup are for the FT8/FT4 modes exclusively. Other contests for these modes are cropping up as well.

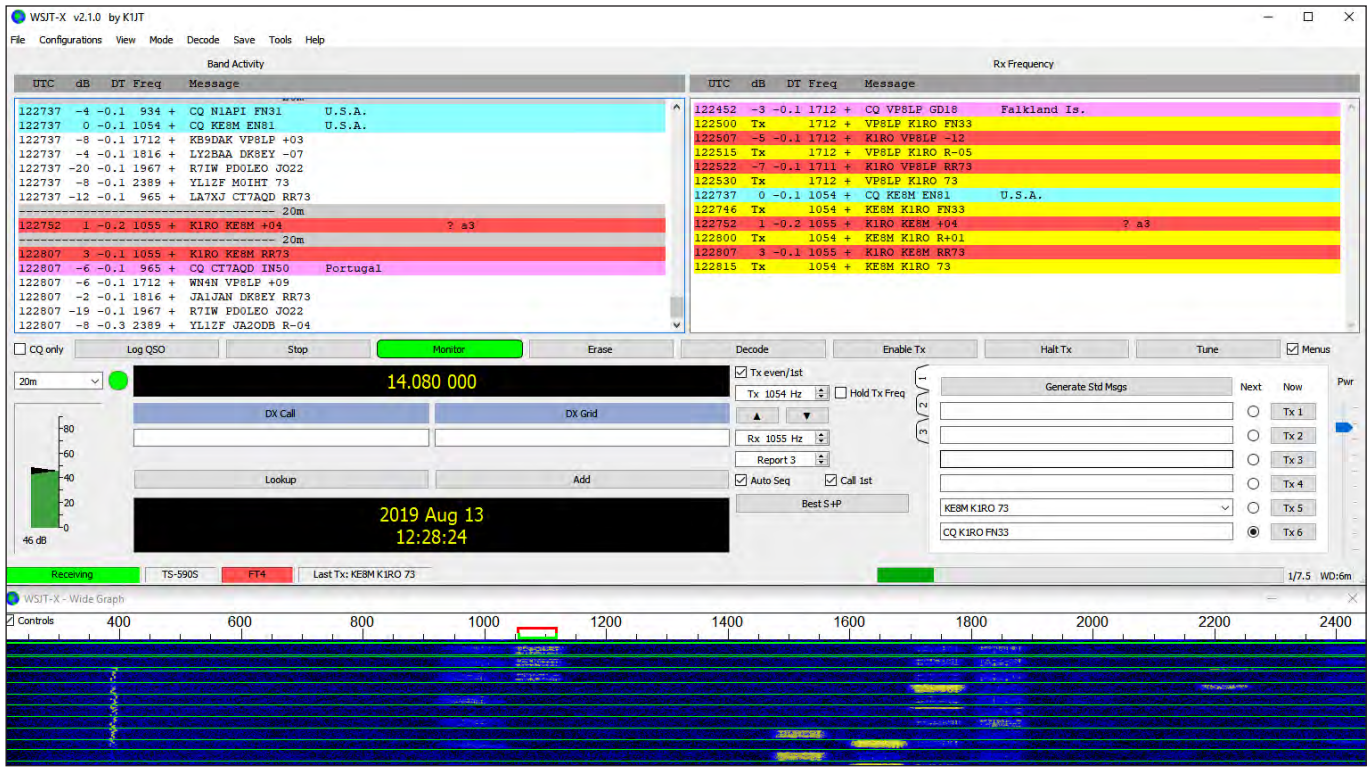

**Figure 35 — FT4, optimized for contesting, uses 7.5 second sequences. Operation is similar to FT8.**

# Digital Basics

This supplement to *The ARRL Handbook* presents digital theory fundamentals and some applications of that theory in Amateur Radio. The fundamentals introduce digital mathematics, including number systems, logic devices and simple digital circuits. Next, the implementation of these simple circuits is explored in integrated circuits, their families and interfacing. Finally, some Amateur Radio applications are discussed involving digital logic, embedded microcontrollers and interfacing to personal computers. This material was written by Dale Botkin, NØXAS, building on material in previous editions by Christine Montgomery, KGØGN and Paul Danzer, N1II.

## 1 Digital vs Analog

An analog signal can represent an infinitely variable indication of voltage, current, frequency, the position of a dial, or some other condition or value. As an example, using a potentiometer as a volume control will give you infinitely variable control over the volume of a signal. In theory, there is no limit to the difference in volume that can be produced. Though the control may be marked from 1 to 10, the actual value would have to be represented by a real number somewhere between 0 and 10. There are an infinite number of settings in between.

In its simplest form, a digital signal simply indicates the *on* or *off* state of some value or input signal. For example, the straight key you may use to key your CW transmitter (or the PTT switch of your voice transmitter) produces an on or off binary signal. In one state the transmitter produces an output signal of some sort; in the other state it does not. Another example is a simple light switch. The light is either on, or it's off. We represent these two states using 0 for off and 1 for on.

Digital electronics gets more interesting when we combine several or many simple on/off digital states to perform more complex tasks. For example, a relatively simple digital circuit can connect the antenna to either the transmitter or the receiver depending on a PTT or other keying signal. It can turn a preamp on or off depending on the state of the transmitter, mute the speaker while transmitting, and even select an antenna based on the selected frequency band. No special digital integrated circuits (chips) are needed to do any of these tasks; we can simply use bipolar transistors or MOSFETs, driven to saturation, as on/off switches. Simple circuits like this can often even be implemented with relays or diodes. The important fact is that the system is digital. There is no "almost transmitting" or "PTT switch partially pressed" state — it's either on, or it's off.

A very useful aspect of digital electronics is our ability to construct simple circuits that can maintain their on/off state indefinitely, until some event causes them to change. These *flip-flop* circuits can be used in various combinations to form *registers* that store information for later use or *counters* that count events and can be read or reset when needed. All of these circuits can be combined in ever larger groups until we finally arrive at the modern microprocessor. A microprocessor can accept input signals from many sources, follow a stored program to perform complex data storage and mathematical calculations, and produce output that we can use to do things that would be far more difficult with analog circuits.

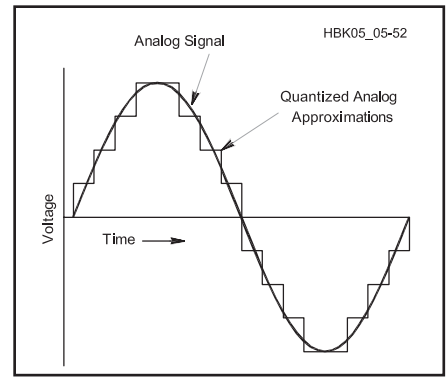

**Figure 1 — An analog signal and its analog approximation. Note that the analog waveform has continuously varying voltage while the approximated waveform is composed of discrete steps.**

So let's revisit our volume control example from the earlier paragraph. Let's assume we have a volume control, but it is used as an input to a digital system that will produce output at the desired level. This is quite

Copyright© 2017 ARRL, all rights reserved.

common in modern equipment, whether it is amateur or consumer gear. Since the control is now digital, we know we can't have an infinite number of values. However, a simple on/off volume control would not be very useful. Using digital electronics, we can break the range between "off" and "fully on" into as many discrete steps as we need. With enough steps, we can give the user of the equipment an approximation of the original analog control while keeping the actual control digital.

By using coding, as discussed in the following pages, the two binary values (off and on, or 0 and 1) can represent any number of real values. **Figure 1** illustrates the contrast of an analog signal (in this case a sine wave) and its digital approximation. Four positive and four negative values are shown as an approximation to the sine wave, but any number of coded value steps can be used as an approximation. The more values are used to approximate the wave, the closer you can come to the actual wave form.

While the focus in this chapter will be on digital theory, many circuits and systems involve *both* digital and analog components. Often, a designer may choose between using digital technology, analog technology or a combination.

# 2 Number Systems

If you have been around computer hobbyists, some of whom are also hams, you may have seen a T-shirt or bumper sticker that reads, "There are 10 kinds of people in the world: those who understand binary, and those who don't." If this has puzzled you in the past, after reading this chapter you will be able to laugh with the rest of us.

In order to understand digital electronics, you must first understand the binary numbering system. Any number system has two distinct characteristics: a set of *symbols* (digits or numerals) and a *base* or radix. A *number* is a collection of these digits, where the left-most digit is the *most significant digit (MSD)* and the right-most digit is the *least significant digit (LSD)*. The value of this number is a weighted sum of its digits. The *weights* are determined by the system's base and the digit's position relative to the decimal point.

While these definitions may seem strange with all the technical terms, they will be more familiar when seen in a decimal system example. See **Table 1**. This is the "traditional" number system with which we are all familiar. In the *base-10* or decimal numbering system we use every day, the digits used are 0 through 9. The weights are powers of ten: $10^0$ or 1 for the right-most column, $10^1$ or 10 for the next column, $10^2$ or 100 for the next and so on. Thus the number 548 represents five hundreds, four tens and eight ones. In this case, 5 is the MSD, and 8 is the LSD. Once you understand this concept, it can be applied to numbering systems using bases other than 10 such as base-2, base-8, or even base-16.

## 2.1 Binary

*Binary* is a *base-2* number system and therefore limited to two symbols: {0, 1}. The weight factors are now powers of 2, like $2^0$, $2^1$ and $2^2$. For example, the decimal number, 163 and its equivalent binary number, 10100011, are shown in **Table 2**.

The digits of a binary number are now *bits* (short for binary digit). The MSD is the *most significant bit (MSB)* and the LSD is the *least significant bit (LSB)*. Four bits make a *nibble* (which you will occasionally see spelled *nybble*) and two nibbles, or eight bits, make a *byte*. The length of a *word* is dependent upon the hardware; it generally can consist of two or four or more bytes, but occasionally will be some other number of bits. These groupings are useful when converting to hexadecimal notation, which is explained later. It is important to remember that while everyone agrees on the meaning of a bit, a nibble (regardless of spelling) and a byte, the meaning of *word* can vary.

Counting in binary follows the same pattern we would use for decimal or any other number system. Consider the three digit binary number XXX. First fill up the right-hand column.

| *Binary Number* | *Decimal Equivalent* |
|---|---|
| **0000** | 0 |
| **0001** | 1 |

The column has been filled, and much quicker than with decimal, since there are only two values instead of 10. But just as we would with a decimal number, we now reset the right-hand column to 0, increase the next column by 1, and continue.

**Table 1**
**Decimal Numbers**

Example: 548

*Digit = 5; Weight = 10; Position = 2*

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| 548 | = | $5(10^2)$ | + | $4(10^1)$ | + | $8(10^0)$ |
| | = | 5(100) | + | 4(10) | + | 8(1) |
| | = | 500 | + | 40 | + | 8 |
| | = | 5 | | 4 | | 8 |
| | | MSD | | | | LSD |

**Table 2**
**Decimal and Binary Number Equivalents**

| | | | | | | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 163 | = | 128 | + | 0 | + | 32 | + | 0 | + | 0 | +0 | + | 2+ | 1 | decimal |
| | = | 1(128) | + | 0(64) | + | 1(32) | + | 0(16) | + | 0(8) | +0(4) | + | 1(2) | +1(1) | |
| | = | $1(2^7)$ | + | $0(2^6)$ | + | $1(2^5)$ | + | $0(2^4)$ | + | $0(2^3)$ | $+0(2^2)$ | + | $1(2^1)$ | $+1(2^0)$ | |
| 10100011 | = | 1 | | 0 | | 1 | | 0 | | 0 | 0 | | 1 | 1 | binary |
| | | MSB | | | | | | | | | | | | LSB | |

Nibble Nibble

Byte = 8 digits

**0010** 2
**0011** 3

Now the first two columns are full, so reset both back to 0 and increase the next column by 1 and continue:

**0100** 4
**0101** 5
**0110** 6
**0111** 7
**1000** 8
…
**1111** 15
And so on.

## 2.2 Hexadecimal

The *hexadecimal*, or hex, *base-16* number system is widely used in computer systems for its ease in conversion to and from binary numbers and the fact that it is somewhat more human-friendly than long strings of 1s and 0s. A base-16 number requires 16 symbols. Since our normal mathematical number, as set up in the decimal system, has only 10 digits (0 through 9), a set of additional new symbols is required. Hex uses both numbers and characters in its set of sixteen symbols: {0, 1, 2, 3, 4, 5,6, 7, 8, 9, A, B, C, D, E, F}. Here, the letters A to F have the decimal equivalents of 10 to 15 respectively: A=10, B=11, C=12, D=13, E=14 and F=15. Again, the weights are powers of the base, such as $16^0$, $16^1$ and $16^2$.

The four-bit binary listing in the previous paragraph shows that the individual 16 hex digits can be represented by a four-bit binary number. Since a byte is equal to eight binary digits, two hex digits provide a byte — the equivalent of 8 binary digits. Conversion from binary to hex is therefore simplified. Take a binary number, divide it into groups of four binary digits starting from the right, and convert each of the four binary digits to an individual value.

Conversion from hex to binary is equally convenient; simply replace each hex digit with its four-bit binary equivalent. As an example, the decimal number 163 is shown in Table 2 as binary 10100011. Divide the binary number in groups of four, so 1010 is equivalent to decimal 10 or "A" hex, and 0011 is equivalent to decimal 3, thus decimal number 163 is equivalent to hex A3.

## 2.3 Binary Coded Decimal (BCD)

The binary number system representation is the most appropriate form for fast internal computations since there is a direct mathematical relationship for every bit in the number. To interface with a human user — who usually wants to see inputs and outputs in terms of decimal numbers — other codes are more useful. The *Binary Coded Decimal (BCD)* system is a simple method for converting binary values to and from decimal for inputs and outputs for user-oriented digital systems. Back in the days when the most common method of presenting output to a user was via seven-segment LED displays, BCD was widely used. Since we now mostly use powerful microprocessors that can easily present information in decimal form, BCD is not nearly as common as it once was. You may, however, run into BCD when using or repairing older digital gear. It is also used in some chips intended for use in digital voltmeters.

In the BCD system, each decimal digit is expressed as a corresponding 4-bit binary number. In other words, the decimal digits 0 to 9 are encoded as the bit strings 0000 to 1001. To make the number easier to read, a space is left between each 4-bit group. For example, the decimal number 163 is equivalent to the BCD number 0001 0110 0011, as shown in **Table 3**.

The important difference between BCD and the previous number systems is that, starting with decimal 10, BCD loses the standard mathematical relationship of a weighted sum. BCD is simply a cut-off hexadecimal. Instead of using the 4-bit code strings 1010 to 1111 for decimal 10 to 15, BCD uses 0001 0000 to 0001 0101. This is one of the reasons that we have moved away from BCD.

## 2.4 Conversion Techniques

An easy way to convert a number from decimal to another number system is to do repeated division, recording the remainders in a tower just to the right. The converted number, then, is the remainders, reading up the tower. This technique is illustrated in **Table 4** for hexadecimal and binary conversions of the decimal number 163.

For example, to convert decimal 163 to hex, repeated divisions by 16 are performed. The first division gives 163/16 = 10 remainder 3. The remainder 3 is written in a column to the right. The second division gives 10/16 = 0 remainder 10. Since 10 decimal = A hex, A is written in the remainder column to the right. This division gave a divisor of 0 so the process is complete. Reading up the remainders column, the result is A3. The most common mistake in this technique is to forget that the Most Significant Digit ends up at the bottom.

Another technique that should be briefly mentioned can be even easier: use a calculator with a binary and/or hex mode option. Many inexpensive and readily available calculators intended for scientific and programming use will convert between number systems quite easily. In addition, calculator programs are available for all types of personal computers regardless of the operating system used.

One warning for this technique: this chapter doesn't discuss negative binary numbers. If your calculator does not give you the answer you expected, it may have interpreted the number as negative. This would happen when the number's binary form has a 1 in its MSB, such as the highest (leftmost) bit for the binary mode's default size. To avoid learning about negative binary numbers the hard way, always use a leading 0 when you enter a number in binary or hex into your calculator.

**Table 3**
**Binary Coded Decimal Number Conversion**

| | 0 0 0 1 | 0 1 1 0 | 0 0 1 1 | **BCD** |
|---|---|---|---|---|
| | = $1(2^0)$ | $1(2^2) + 1(2^1)$ | $1(2^1) + 1(2^0)$ | |
| | = (1) | (4 + 2) | (2 + 1) | |
| 163 | = 1 | 6 | 3 | **decimal** |

**Table 4**
**Number System Conversions**

| *Hex* | | *Remainder* | | *Binary* | | *Remainder* | |
|---|---|---|---|---|---|---|---|
| 16 | \|163 | | | 2 | \|163 | | |
| | \|10 | 3 | LSB | | \|81 | 1 | LSB |

| A3 hex | | | | 1010 0011 binary | | | |

# 3 Physical Representation of Binary States

## 3.1 State Levels

Most digital systems use the binary number system because many simple physical systems are most easily described by two state levels (0 and 1). For example, the two states may represent "on" and "off" or a "mark" and "space" in a communications transmission. In electronic systems, state levels are physically represented by voltages. A typical choice is
state 0 = 0 V
state 1 = 5 V

Since it is unrealistic to obtain these exact voltage values, a more practical choice is a range of values, such as
state 0 = 0.0 to 0.4 V
state 1 = 2.4 to 5.0 V

**Figure 2** illustrates this representation of states by voltage levels. The undefined region between the two binary states is also known as the *transition region* or *noise margin*.

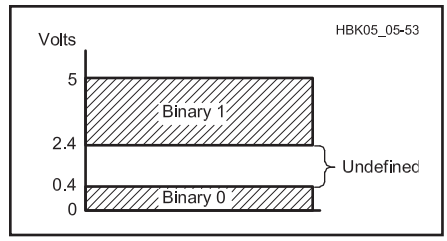

**Figure 2 — Representation of binary states 1 and 0 by a selected range of voltage levels.**

## 3.2 Transition Time

The gap in Figure 2, between binary 0 and binary 1, shows that a change in state does not occur instantly. There is a *transition time* between states. This transition time is a result of the time it takes to charge or discharge the stray capacitance in wires and other components because voltage cannot change instantaneously across a capacitor. (Stray inductance in the wires also has an effect because the current through an inductor can't change instantaneously.) The transition from a 0 to a 1 state is called the *rise time*, and is usually specified as the time for the pulse to rise from 10% of its final value to 90% of its final value. Similarly, the transition from a 1 to a 0 state is called the *fall time*, with a similar 10% to 90% definition. Note that these times need not be the same. **Figure 3A** shows an ideal signal, or *pulse*, with zero-time switching. Figure 3B shows a typical pulse, as it changes between states in a smooth curve.

Rise and fall times vary with the logic family used and the location in a circuit. Typical values of transition time are in the microsecond to nanosecond range. In a circuit, distributed inductances and capacitances in wires or PC-board traces may cause rise and fall times to increase as the pulse moves away from the source. One reason rise and fall times may be of interest to the radio designer is because of the possibility of generating RF noise in a digital circuit.

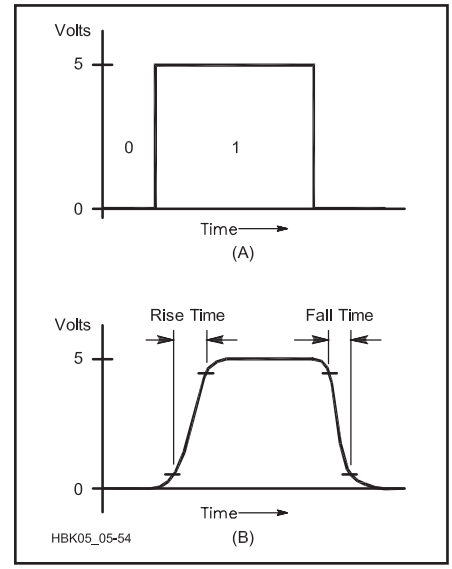

**Figure 3 — (A) An ideal digital pulse and (B) a typical actual pulse, showing the gradual transition between states.**

## 3.3 Propagation Delay

Rise and fall times only describe a relationship within a pulse. For a circuit, a pulse input into the circuit must propagate through the circuit; in other words it must pass through each component in the circuit until eventually it arrives at the circuit output. The time delay between providing an input to a circuit and seeing a response at the output is the *propagation delay* and is illustrated by **Figure 4.**

For modern switching logic, typical propagation delay values are in the 1 to 15 nanosecond range. (It is useful to remember that the propagation delay along a wire or printed-circuit-board trace is about 1.0 to 1.5 ns per inch.) Propagation delay is the result of cumulative transition times as well as transistor switching delays, reactive element charging times and the time for signals to travel through wires. In complex circuits, different propagation delays through different paths can cause problems when pulses must arrive somewhere at exactly the same time.

The effect of these delays on digital devices can be seen by looking at the speed of the digital pulses. Most digital devices use *clock pulses*. If two pulses are supposed to arrive at a logic circuit at the same time, or very close to the same time, the path length for the two signals cannot be any different than two to three inches. This can be a very significant design problem for high-speed logic designs.

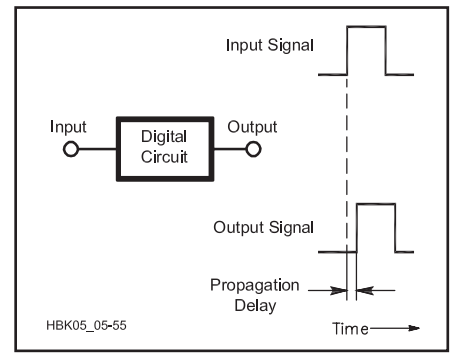

**Figure 4 — Propagation delay in a digital circuit.**

# 4 Combinational Logic

Having defined a way to use voltage levels to physically represent digital numbers, we can apply digital signal theory to design useful circuits. Digital circuits combine binary inputs to produce a desired binary output or combination of outputs. This simple combination of 0s and 1s can become very powerful, implementing everything from simple switches to powerful computers.

A digital circuit falls into one of two types: combinational logic or sequential logic. In a *combinational logic* circuit, the output depends only on the *present inputs* (if we ignore propagation delay). In contrast, in a *sequential logic* circuit, the output depends on the present inputs, the *previous sequence of inputs* and often a clock signal. Later sections of this chapter will examine some circuits built using the basics established here.

## 4.1 Boolean Algebra and the Basic Logical Operators

Combinational circuits are composed of logic gates, which perform binary operations. Logic gates manipulate binary numbers, so you need an understanding of the algebra of

binary numbers to understand how logic gates operate. *Boolean algebra* is the mathematical system used to describe and design binary digital circuits. It is named after George Boole, the mathematician who developed the system. Standard algebra has a set of basic operations: addition, subtraction, multiplication and division. Similarly, Boolean algebra has a set of basic operations, called *logical operations*: NOT, AND and OR.

The function of these operators can be described by either a Boolean equation or a truth table. A Boolean *equation* describes an operator's function by representing the inputs and the operations performed on them. An equation is of the form "B = A," while an *expression* is of the form "A." In an assignment equation, the inputs and operations appear on the right and the result, or output, is assigned to the variable on the left.

A *truth table* describes an operator's function by listing all possible inputs and the corresponding outputs. Truth tables are sometimes written with Ts and Fs (for true and false) or with their respective equivalents, 1s and 0s. In company databooks (catalogs of logic devices a company manufactures), truth tables are usually written with Hs and Ls (for high and low). In the figures, 1 will mean high and 0 will mean low. This representation is called positive logic. The meaning of different logic types and why they are useful is discussed in a later section.

Each Boolean operator also has two circuit symbols associated with it. The traditional symbol — used by ARRL and other US publications — appears on top in each of the figures; for example, the triangle and bubble for the NOT function in Figure 7. In the traditional symbols, a small circle, or *bubble*, always represents "NOT." (This *bubble* is called a state indicator.)

Appearing just below the traditional symbol is the newer ANSI/IEEE Standard symbol. This symbol is always a square box with notations inside it. In these newer symbols, a small triangular flag represents "NOT." The new notation is an attempt to replace the detailed logic drawing of a complex function with a simpler block symbol. Adoption of the newer symbols has been spotty, and you are therefore still more likely to see the traditional symbols for basic logic functions than the ANSI/IEEE symbols.

## 4.2 Common Gates

**Figu**res **5**, **6** and **7** show the truth tables, Boolean algebra equations and circuit symbols for the three basic Boolean operations: AND, OR and NOT, respectively. All combinational logic functions, no matter how complex, can be described in terms of these three operators. Each truth table can be converted into words. The truth table for the two-input AND gate can be expressed as "the output C is a 1 only when the inputs are both 1s." This can be seen by examining the output column C — it remains at a 0 and becomes a 1 only when the input column A and the input column B are both 1s — the last line of the table.

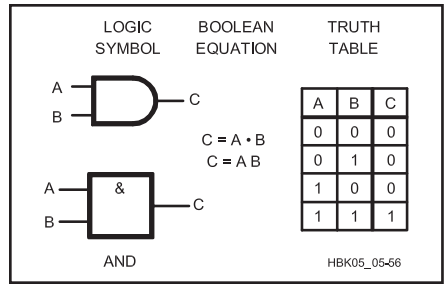

**Figure 5 — Two-input AND gate.**

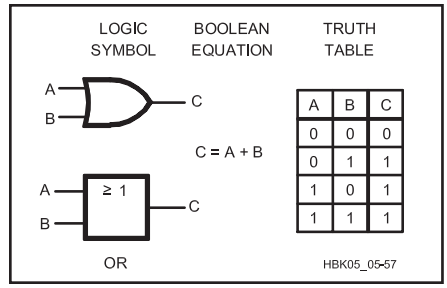

**Figure 6 — Two-input OR gate.**

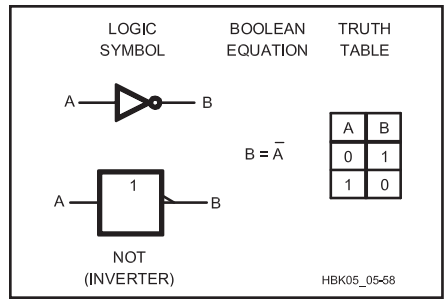

**Figure 7 — Inverter.**

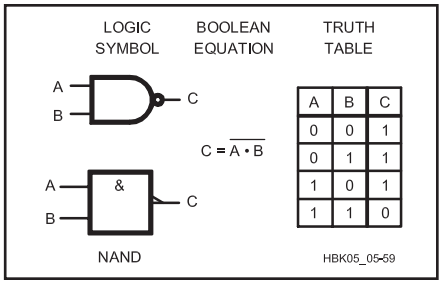
The NOT operation is also called *inversion*, *negation* or *complement*. The circuit that implements this function is called an *inverter* or *inverting buffer*. The most common notation for NOT is a bar over a variable or expression. For example, NOT A is denoted $\overline{A}$. This is read as either "Not A" or as "A bar." A less common notation is to denote Not A by A', which is read as "A prime." You will also see various other notations in schematic diagrams and component data sheets, such as a leading exclamation point or has symbol — !A or #A indicating "Not A."

While the inverting buffer and the noninverting buffer covered later have only one input and output, many combinational logic elements can have multiple inputs. When a combinational logic element has two or more inputs and one output, it is called a *gate*. (The term "gate" has a number of different but specific technical uses. For a clarification of the many definitions of gate, see the section on **Synchronicity and Control Signals**, later in this chapter.) For simplicity, the figures and truth tables for multiple-input elements will show the operations for only two inputs, the minimum number. Remember, though, that it is quite common to have gates with more than two inputs. A three-, four-, or eight-input gate works in the exact same manner as a two-input gate.

The output of an AND function is 1 only if *all* of the inputs are 1. Therefore, if *any* of the inputs are 0, then the output is 0. The notation for an AND is either a dot (•) between the inputs, as in C = A•B, or nothing between the inputs, as in C = AB. Read these equations as "C equals A AND B."

The OR gate detects if one or more inputs are 1. In other words, if *any* of the inputs are 1, then the output of the OR gate is 1. Since this includes the case where more than one input may be 1, the OR operation is also known as an INCLUSIVE OR. The OR operation detects if *at least one* input is 1. Only if all the inputs are 0, then the output is 0. The notation for an OR is a plus sign (+) between the inputs, as in C = A + B. Read this equation as "C equals A OR B."

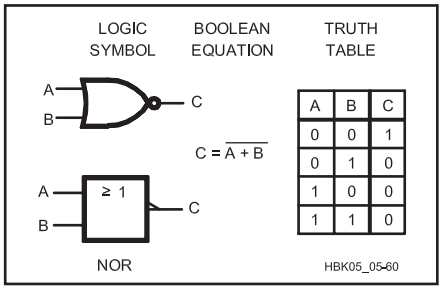
## 4.3 Additional Gates



More complex logical functions are derived from combinations of the basic logical operators. These operations — NAND, NOR, XOR and the noninverter or buffer — are illustrated in **Figures 8** through **11**, respectively. As before, each is described by a truth table, Boolean algebra equation and circuit symbols. Also as before, except for the noninverter, each could have more inputs than the two illustrated.

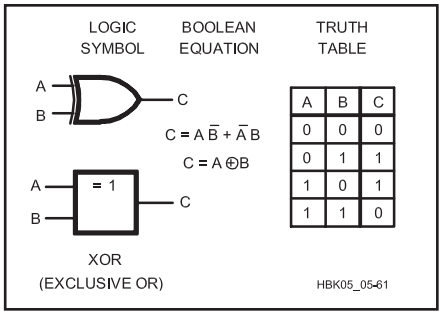
The NAND gate (short for NOT AND) is equivalent to an AND gate followed by a NOT gate. Thus, its output is the complement of the AND output: The output is a 0 only if all the inputs are 1. If any of the inputs is 0, then the output is a 1.

The NOR gate (short for NOT OR) is equivalent to an OR gate followed by a NOT gate. Thus, its output is the complement of the OR output: If any of the inputs are 1, then the output is a 0. Only if all the inputs are 0, then the output is a 1.



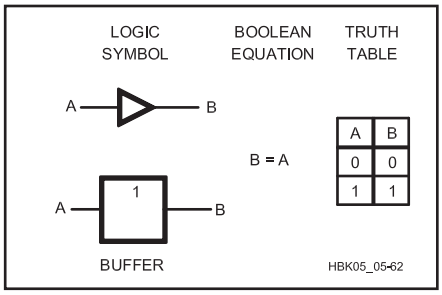
The operations so far enable a designer to determine two general cases: (1) if *all* inputs have a desired state or (2) if *at least one* input has a desired state. The XOR and XNOR gates enable a designer to determine if *one and only one* input of a desired state is present.

The XOR gate (read as EXCLUSIVE OR) is a combination of an OR and a NAND gate. It has an output of 1 if one and only one of the inputs is a 1 state. The output is 0 otherwise. The symbol for XOR is ⊕. This is easy to remember if you think of the "+" OR symbol



| A | B | C |
|---|---|---|
| 0 | 0 | 1 |
| 0 | 1 | 1 |
| 1 | 0 | 1 |
| 1 | 1 | 0 |

**Figure 8 — Two-input NAND gate.**



| A | B | C |
|---|---|---|
| 0 | 0 | 1 |
| 0 | 1 | 0 |
| 1 | 0 | 0 |
| 1 | 1 | 0 |

**Figure 9 — Two-input NOR gate.**

| A | B | C |
|---|---|---|
| 0 | 0 | 0 |
| 0 | 1 | 1 |
| 1 | 0 | 1 |
| 1 | 1 | 0 |

**Figure 10 — Two-input XOR gate.**

| A | B |
|---|---|
| 0 | 0 |
| 1 | 1 |

**Figure 11 — Noninverting buffer.**

enclosed in an "O" for *only one*.

The XOR gate is also known as a "half adder," because in binary arithmetic it does everything but the "carry" operation. The following examples show the possible binary additions for a two-input XOR.

| | | | | |
|---|---|---|---|---|
| A | 0 | 0 | 1 | 1 |
| B | 0 | 1 | 0 | 1 |
| Sum | 0 | 1 | 1 | 0 |

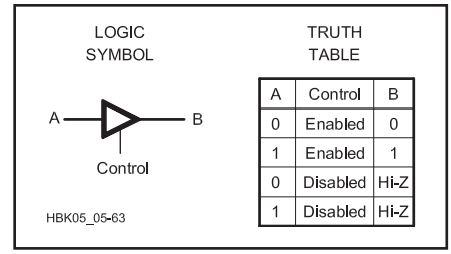
The XNOR gate (read as EXCLUSIVE NOR) is the complement of the XOR gate. The output is 0 if one and only one of the inputs is a 1. The output is 1 either if all inputs are 0 or more than one input is 1.

### NONINVERTERS (BUFFERS)

A *noninverter*, also known as a *buffer*, *amplifier* or *driver*, at first glance does not seem to do anything. It simply receives an input and produces the same output. In reality, it is changing other properties of the signal in a useful fashion, such as amplifying the current level. While not useful for logical operations, applications of a noninverter include providing sufficient current to drive a number of gates or some other circuit such as a relay; interfacing between two logic families; obtaining a desired pulse rise time; and providing a slight delay to make pulses arrive at the proper time.

### TRI-STATE GATES

Under normal circumstances, a logic element can drive or feed several other logic elements. A typical AND gate might be able to drive or feed 10 other gates. This is known as *fan-out*. However, with certain exceptions only one gate output can be connected to a single wire. If you have two possible driving sources to feed one particular wire, some logic network that probably includes a number OR gates must be used.



In many applications, including computers, data is routed internally on a set of wires called *buses*. The data on the bus can come from many circuits or drivers, and many other devices may be *listening* on the bus. To eliminate the need for the network of OR gates to drive each bus wire, a set of gates known as *tri-state* gates are used.

The symbol and truth table for a tri-state gate are shown in **Figure 12**. A tri-state gate can be any of the common gates previously described, but with one additional control lead. When this lead is enabled (it can be designed to allow either a 0 or a 1 to enable it) the gate operates normally, according to the truth table for that type of gate. However, when the gate is not enabled, the output goes to a high impedance (Hi-Z), and so far as the output wire is concerned, the gate does not exist.

Each device that has to send data down a bus wire is connected to the bus wire through a tri-state gate. However, as long as only one device, through its tri-state gate, is enabled, it is as though all the other connected tri-state gates do not exist.

## 4.4 Boolean Theorems

The analysis of a circuit starts with a logic diagram and then derives a circuit description. In digital circuits, this description is in the form of a truth table or logical equation. The

| A | Control | B |
|---|---|---|
| 0 | Enabled | 0 |
| 1 | Enabled | 1 |
| 0 | Disabled | Hi-Z |
| 1 | Disabled | Hi-Z |

**Figure 12 — Tri-State gate.**

*synthesis*, or design, of a circuit goes in the reverse: starting with an informal description, determining an equation or truth table and then expanding the truth table to components that will implement the desired response. In both of these processes, we need to either simplify or expand a complex logical equation.

To manipulate an equation, we use mathematical *theorems*. Theorems are statements that have been proven to be true. The theorems of Boolean algebra are very similar to those of standard algebra, such as commutivity and associativity. Proofs of the Boolean algebra theorems can be found in an introductory digital design textbook.

### BASIC THEOREMS

**Table 5** lists the theorems for a single variable and **Table 6** lists the theorems for two or more variables. These tables illustrate the *principle of duality* exhibited by the Boolean theorems: Each theorem has a dual in which, after swapping all ANDs with ORs and all 1s with 0s, the statement is still true.

The tables also illustrate the *precedence* of the Boolean operations: the order in which operations are performed when not specified by parenthesis. From highest to lowest, the precedence is NOT, AND then OR. For example, the distributive law includes the expression "A + B•C." This is equivalent to

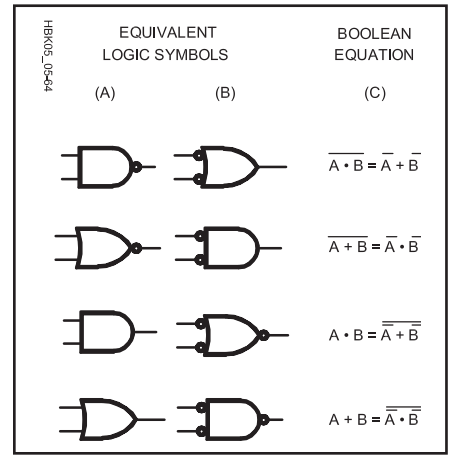


**Figure 13 — Equivalent gates from DeMorgan's Theorem: Each gate in column A is equivalent to the opposite gate in column B. The Boolean equations in column C formally state the equivalences.**

"A + (B•C)." The parenthesis around (B•C) can be left out since an AND operation has higher priority than an OR operation. Precedence for Boolean algebra is similar to the convention of standard algebra: raising to a power, then multiplication, then addition.

### DeMORGAN'S THEOREM

One of the most useful theorems in Boolean algebra is DeMorgan's Theorem:

$\overline{A \bullet B} = \overline{A} + \overline{B}$

and its dual

$\overline{A + B} = \overline{A} \bullet \overline{B}.$

**Table 5**
**Boolean Algebra Single Variable Theorems**

| | | |
|---|---|---|
| Identities: | A • 1 = A | A + 0 = A |
| Null elements: | A • 0 = 0 | A + 1 = 1 |
| Idempotence: | A • A = A | A + A = A |
| Complements: | A • $\overline{A}$ = 0 | A + $\overline{A}$ = 1 |
| Involution: | $\overline{(A)}$ = A | |

The truth table in **Table 7** proves these statements. DeMorgan's Theorem provides a way to simplify the complement of a large expression. It also enables a designer to interchange a number of equivalent gates, as shown by **Figure 13**.

The equivalent gates show that the duality principle works with symbols the same as it does for Boolean equations: just swap ANDs with ORs and switch the bubbles. For example, the NAND gate — an AND gate followed by an inverter bubble — becomes an OR gate preceded by two inverter bubbles. DeMorgan's Theorem is important because it means any logical function can be implemented using either inverters and AND gates or inverters and OR gates. Also, the ability to change placement of the bubbles using DeMorgan's Theorem is useful in dealing with mixed logic, to be discussed next.

### POSITIVE AND NEGATIVE LOGIC

The truth tables shown in the figures in this chapter are drawn for positive logic. In *positive logic*, or *high true*, a higher voltage means true (logic 1) while a lower voltage means false (logic 0). This is also referred to as *active high*: a signal performs a named action or denotes a condition when it is "high" or 1. In *negative logic*, or *low true*, a lower voltage means true (1) and a higher voltage means false (0). An *active low* signal performs an action or denotes a condition when it is "low" or 0.

In both logic types, true = 1 and false = 0; but whether true means high or low differs. Company databooks are drawn for general truth tables: an H for high and an L for low. (Some tables also have an X for a "don't care" state. "Don't care" means that the output does not depend on the state of that variable.) The function of the table can differ depending on whether it is interpreted for positive logic or negative logic.

Device data sheets often show positive logic convention, or positive logic is assumed. However, a signal into an IC is represented with a bar above it, indicating that the "enable" on that wire is active low — it does *not* mean negative logic (0 V = a logical 1) is used! Similarly a bubble on the input of a logic element also usually means active low. These can be sources of confusion.

**Figure 14** shows how a general truth table differs when interpreted for different logic types. The same truth table gives two equivalent gates: positive logic gives the function of

**Table 6**

a NAND gate while negative logic gives the function of a NOR gate.

Note that these gates correspond to the equivalent gates from DeMorgan's Theorem. A bubble on an input or output terminal indicates an active low device. The absence of bubbles indicates an active high device.

Like the bubbles, signal names can be used to indicate logic states. These names can aid the understanding of a circuit by indicating control of an action (GO, /ENABLE) or detection of a condition (READY, /ERROR). The action or condition occurs when the signal is in its active state. When a signal is in its active state, it is called *asserted*; a signal not in its active state is called *negated* or *deasserted*.

A prefix can easily indicate a signal's active state. Active low signals are preceded by a symbol such as /, |, ! or # (for example /READY or !READY). Active low signals are also denoted by an overscore, such as $\overline{CL}$. Active high signals have no prefix or overscore. As an example, see the truth table for a flip-flop later in this chapter. Standard practice is that the signal name and input pin match (have the same active level). For example, an input with a bubble (active low) may be called /READY, while an input with no bubble (active high) is called READY. Output signal names should always match the device output pin.

In this chapter, positive logic is used unless indicated otherwise. Although using mixed logic can be confusing, it does have some advantages. Mixed logic combined with DeMorgan's Theorem can promote more effective use of available gates. Also, well-chosen signal names and placement of bubbles can promote more understandable logic diagrams.

# 5 Sequential Logic

The previous section discussed combinational logic, whose outputs depend only on the present inputs. In contrast, in *sequential logic* circuits, the new output depends not only on the present inputs but also on the present outputs. The present outputs depended on the previous inputs and outputs and those earlier outputs depended on even earlier inputs and outputs and so on. Thus, the present outputs depend on the previous *sequence of inputs* and the system has *memory*. Having the outputs become part of the new inputs is known as *feedback*.

## 5.1 Synchronicity and Control Signals

When a combinational circuit is given a set of inputs, the outputs take on the expected values after a propagation delay during which the inputs travel through the circuit to the output. In a sequential circuit, however, the travel through the circuit is more complicated. After application of the first inputs and one propagation delay, the outputs take on the resulting state; but then the outputs start trickling back through and, after a second propagation delay, new outputs appear. The same happens after a third propagation delay. With propagation delays in the nanosecond range, this cycle around the circuit is rapidly and continually generating new outputs. A user needs to know when the outputs are valid.

There are two types of sequential circuits: synchronous circuits and asynchronous circuits, which are analyzed differently for valid outputs. In *asynchronous* operation, the outputs respond to the inputs immediately after the propagation delay. To work properly, this type of circuit must eventually reach a *stable* state: the inputs and the fed back outputs result in the new outputs staying the same. When the nonfeedback inputs are changed, the feedback cycle needs to eventually reach a new stable state. Generally, the output of this type of logic is not valid until the last input has changed, and enough time has elapsed for all propagation delays to have occurred.

In *synchronous* operation, the outputs change state only at specific times. These times are determined by the presence of a particular input signal: a clock, toggle, latch or enable. Synchronicity is important because it ensures proper timing: all the inputs are present where needed when the control signal causes a change of state.

### CONTROL SIGNALS

Some authors vary the meanings slightly for the different control signals. The following is a brief illustration of common uses, as well as showing uses for noun, verb and adjective. *Enabling* a circuit generally means the control signal goes to its asserted level, allowing the circuit to change state. *Latch* implies memory: a latch circuit can store a bit of information. A latch signal can cause a circuit to keep its present state indefinitely. *Gate* can have several meanings, some unrelated to synchronous control. For example, a gate can be a signal used to trigger the passage of other signals through a circuit. A gate can also be a logic circuit with two or more inputs and one output, as used earlier in this chapter. Of course, "gate" can also be one of the electrodes of an FET as described in another chapter. To *toggle* means a signal changes state, from 1 to 0 or vice versa. A *clock* signal is one that toggles at a regular rate.

Clock control is the most common method of synchronizing logic circuits, so it has some additional terms as illustrated by **Figure 15**. The *clock period* is the time between successive transitions in the same direction; the *clock frequency* is the reciprocal of the period. A *pulse* or *clock tick* is the first edge in a clock period, or sometimes the period itself or the first half of the period. The *duty cycle* is the percentage of time that the clock signal is at its asserted level. A common application of the use of clock pulses is to limit the input to a logic circuit such that the circuit is only enabled on one clock phase; that is the inputs occur before the clock changes to a logic 1.

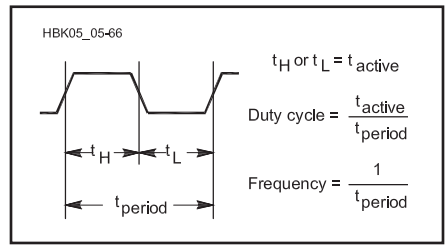

**Figure 15 — Clock signal terms. The duty cycle would be $t_H$ / $t_{PERIOD}$ for an active high signal and $t_L$ / $t_{PERIOD}$ for an active low signal.**

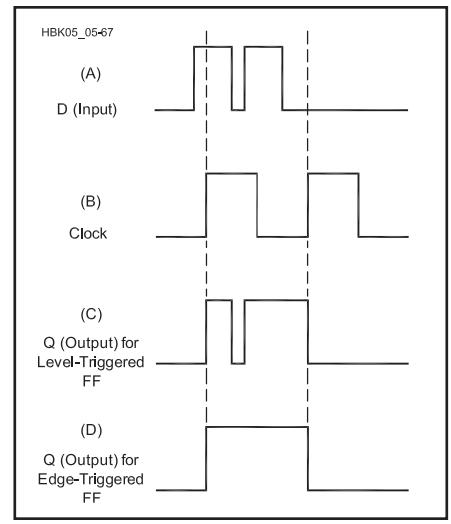

**Figure 16 — Level-triggered vs edge-triggered for a D flip-flop: (A) D input, (B) clock input, (C) output Q for level-triggered: circuit responds whenever clock is 1. (D) output Q for edge-triggered: circuit responds only at rising edge of clock. Notice that the short negative pulse on the D input is not reproduced by the edge-triggered flip-flop.**

The outputs are sampled only after this point; perhaps when the clock next changes back to a logic 0.

The reaction of a synchronous circuit to its control signal is *static* or *dynamic*. Static, *gated* or *level-triggered* control allows the circuit to change state whenever the control signal is at its active or asserted level. Dynamic, or *edge-triggered*, control allows the circuit to change state only when the control signal *changes* from unasserted to asserted. By convention, a control signal is active high if state changes occur when the signal is high or at the rising edge and active low in the opposite case. Thus, for positive logic, the convention is enable = 1 or enable goes from 0 to 1. This transition from 0 to 1 is called *positive edge-triggered* and is indicated by a small triangle inside the circuit box. A circuit responding to the opposite transition, from 1 to 0, is called *negative edge-triggered*, indicated by a bubble with the triangle.

Whether a circuit is level-triggered or edge-triggered can affect its output, as shown by **Figure 16**. The D input includes a very brief pulse, called a *glitch*, which may be caused by noise. The differing results at the output illustrate how noise can cause errors. We have both edge and level triggered circuits available so that we can meet the requirements of our particular design.

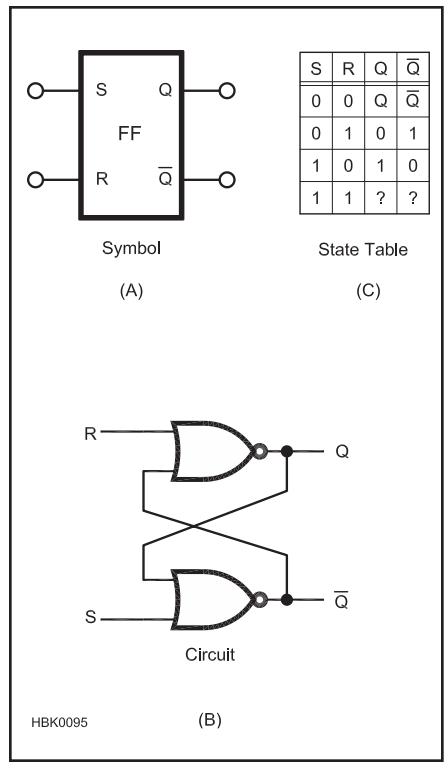

**Figure 17 — Unclocked S-R Flip-Flop. (A) schematic symbol. (B) circuit diagram. (C) state table or truth table.**

build S-R flip-flops out of gates for jobs such as switch contact debouncing. In **Figure 17** the symbol for an S-R flip flop and its truth table are accompanied by a logic implementation, using NOR gates. As the truth table shows, this basic implementation requires a positive or logic 1 input on the set input to put the flip-flop in the Q or set state. Remove the input, and the flip flop stays in the Q state, which is what is expected of a flip-flop. Not until the S input receives a logic 1 input does the flip- flop change state and go to the reset or Q=0 state.

Note that the input can be a short pulse or a level; as long as it is there for some minimum duration (established by the propagation delay of the gates used), the flip-flop will respond. By contrast the clocked S-R flip-flop in **Figure 18** requires both a positive level to be present at either the S or R inputs and a positive clock pulse. The clock pulse is ANDed with the S or R input to trigger the flip–flop. In this case the flip-flop shown is implemented with a set of NOR gates.

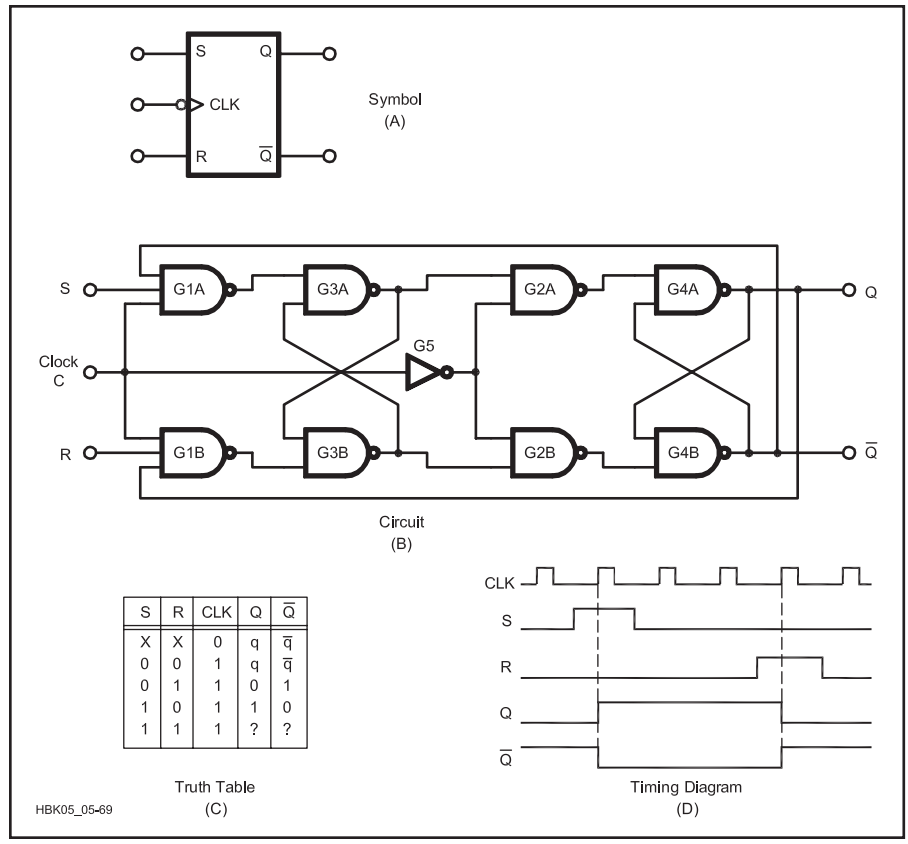
A final triggering method is edge triggering. Here, instead of using the clock pulse as shown in the timing diagram of Figure 18, just the edge of the clock pulse is used. The edge-triggered flip-flop helps solves a problem with noise. Edge-triggering minimizes the time during which a circuit responds to its

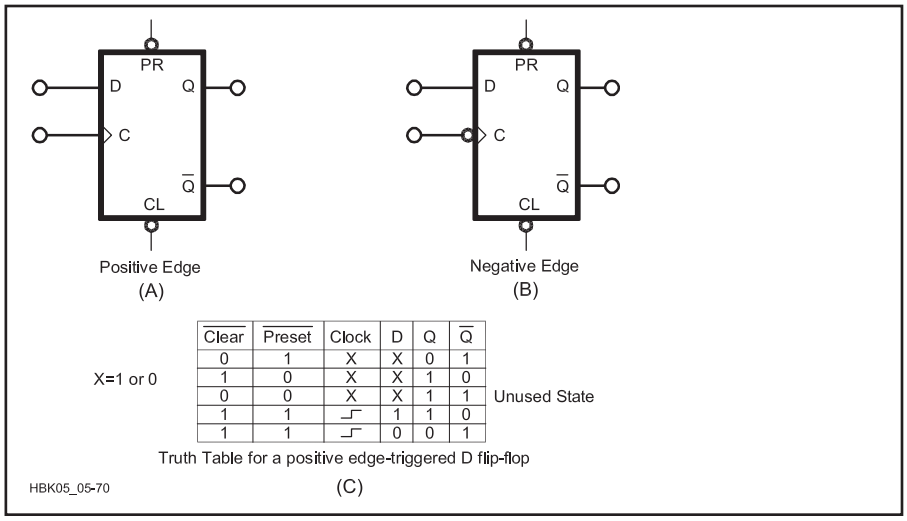
## 5.2 Flip-Flops

Flip-flops are the basic building blocks of sequential circuits. A *flip-flop* is a device with two stable states: the *set* state (1) and the *reset* or *cleared* state (0). The flip-flop can be placed in one or the other of the two states by applying the appropriate input. Since a common use of flip-flops is to store one bit of information, some use the term *latch* interchangeably with flip-flop. A set of latches, or flip-flops holding an n-bit number is called a *register*. While gates have special symbols, the schematic symbol for most sequential logic components is a rectangular box with the circuit name or abbreviation, the signal names and assertion bubbles. For flip-flops, the circuit name is usually omitted since the signal names are enough to indicate a flip-flop and its type. The four basic types of flip-flops are the S-R, D, T and J-K. The most common flip-flops available to Amateurs today are the J-K and D- flip-flops; the others can be synthesized if needed by utilizing these two varieties. Table 8 provides a summary of symbols and truth tables for these four types of flip-flops.

### TRIGGERING A FLIP-FLOP

Although the S-R (Set-reset) flip flop is no longer generally available or used, it does provide insight in basic flip-flop operations and triggering. It is also not uncommon to





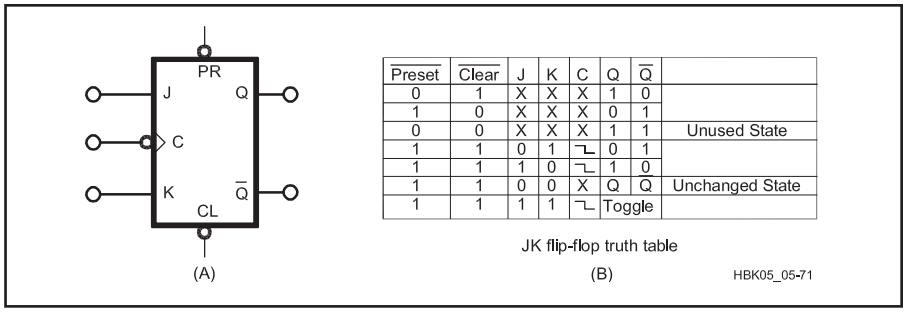


**Figure 18 — Master-Slave Flip-Flop. (A) logic symbol. (B) NAND gate implementation. (C) truth table. (D) timing diagram.**

inputs: the chance of a glitch occurring during the nanosecond transition of a clock pulse is remote. A side benefit of edge-triggering is that only one new output is produced per clock period. Edge-triggering is denoted by a small rising-edge or falling-edge symbol in the clock column of the flip-flop's truth table. It can also appear, instead of the clock triangle, inside the schematic symbol.

## MASTER/SLAVE FLIP-FLOP

One major problem with the simple flip-flop shown up to now is the question of when is there a valid output. Suppose a flip-flop receives input that causes it to change state; at the same time the output of this flip-flop is being sampled to control some other logic element. There is a real risk here that the output will be sampled just as it is changing and thus the validity of the output is questionable.

A solution to this problem is a circuit that samples and stores its inputs before changing its outputs. Such a circuit is built by placing two flip-flops in series; both flip-flops are triggered by a common clock but an inverter on the second flip-flop's clock input causes it to be asserted only when the first flip-flop is not asserted. The action for a given clock pulse is as follows: The first, or master, flip-flop can change only when the clock is high, sampling and storing the inputs. The second, or slave, flip-flop gets its input from the master and changes when the clock is low. Hence, when the clock is 1, the input is sampled; then when the clock becomes 0, the output is generated. Note that a bubble may appear on the schematic symbol's clock input, reminding us that the output appears when the clock is asserted low. This is conventional for TTL-style J-K flip-flops, but it can be different for CMOS devices.

The master/slave method isolates output changes from input changes, eliminating the problem of series-fed circuits. It also ensures only one new output per clock period, since the slave flip-flop responds to only the single sampled input. A problem can still occur, however, because the master flip-flop can change more than once while it is asserted; thus, there is the potential for the master to sample at the wrong time. There is also the potential that either flip-flop can be affected by noise.

A master-slave, S-R clocked input flip-flop synthesized from NAND gates, Figure 18B, is accompanied by its logic symbol, Figure 18A. From the logic symbols you can tell that the output changes on a negative-going clock edge.

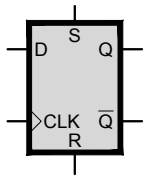
G3A and G3B form the master set-rest flip-flop, and G4A and G4B the slave flip flop. The input signals S and R are controlled by the positive going edge of the clock through gates G1A and G1B. G2A and G2B control the inputs into the slave flip-flop; these inputs are the outputs of the master flip-flop. Note G5 inverts the clock; thus while the positive-going edge places new data into the master flip-flop, the other edge of the clock transfers the output of the master into the slave on the following negative clock edge.

## D FLIP-FLOP

In a D (data) flip-flop, the *data* input is transferred to the outputs when the flip-flop is enabled. The logic level at the D input is transferred to Q when the clock is positive; the Q output retains this logic level until the next positive clock pulse (see **Figure 19**). The truth table summarizes this operation. If D = 1 the next clock pulse makes Q = 1. If D = 0, the next clock pulse makes Q = 0. A D flip-flop is useful to store one bit of information. A collection of D flip-flops forms a register.

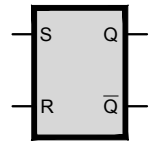
## J-K FLIP-FLOP

The J-K flip-flop, shown schematically in **Figure 20A**, has five inputs. The unit shown uses both positive active inputs (the J and K inputs) and negative active inputs (note the bubbles on the C or clock, PR or preset and CL or clear inputs). With these inputs almost any other type of flip-flop may be synthesized.



The truth table of Figure 20B provides an explanation. Lines (rows) 1 and 2 show the preset and clear inputs and their use. These are active low, meaning that when one (and only one) of them goes to a logic 0, the flip-flop responds, just as if it was a S-R or set-reset flip-flop. Make PR a logic 0, and leave CL a logic 1, and the flip-flop goes into the Q = 1 state (line 1). Do the reverse (line 2) – PR = 1, CL = 0 and the flip-flop goes into a Q' = 1 state. When these two inputs are used, J, K and C are marked as X or don't care, because the PR and CL inputs override them. Line 3 corresponds to the unused state of the R-S flip-flop.

Line 5 shows that if J = 1 and K = 0, the next clock transition from high to low sets Q = 1 and Q' = 0. Alternately, line 4 shows J = 0 and K = 1 sets Q = 0 and Q' = 1. Therefore if a signal is applied to J, and the inverted signal sent to K, the J-K flip-flop will mimic a D flip-flop, echoing its input.



The most unique feature of the J-K flip-flop is line 7. If both J and K are connected to a 1, then each clock 1 to 0 transition will flip or toggle the flop-flop. Thus the J-K flip-flop can be used as a T flip-flop, as in a ripple counter (see the following **Counters** section.)

**Table 8**

## 5.3 Groups of Flip-Flops

### COUNTERS

Groups of flip-flops can be combined to make counters. Intuitively, a counter is a circuit that starts at state 0 and sequences up through states 1, 2, 3, to m, where m is the maximum number of states available. From state m, the next state will return the counter to 0. This describes the most common counter: the *n-bit binary counter*, with n outputs corresponding to $2^n$ = m states. Such a counter can be made from n flip-flops, as shown in **Figure 21**. This figure shows implementations for each of the types of synchronicity. Both circuits pass the data count from stage to stage. In the asynchronous counter, Figure 21A, the clock is also passed from stage to stage and the circuit is called *ripple* or *ripple-carry*.

The J-K flip-flop truth table shows that with PR (Preset) and CL (Clear) both positive, and therefore not effecting the operation, the flip-flop will toggle if J and K are tied to a logic 1. In Figure 21A the first stage has its J and K inputs permanently tied to a logic 1, and each succeeding stage has its J and K inputs tied to Q of the proceeding stage. This provides a direct ripple counter implementation.

Design of a synchronous counter is bit more involved. It consists of determining, for a particular count, the conditions that will make the next stage change at the same clock edge when all the stages are changing.

To illustrate this, notice the binary counting table of Figure 21. The right-hand column represents the lowest stage of the counter. It alternates between 1 and 0 on every line. Thus, for the first stage the J and K inputs are tied to logic 1. This provides the alternation required by the counting table.

The middle column or second stage of the counter changes state right after the lower stage is a 1 (lines C, E and G). Thus if the Q output of the lowest stage is tied to the J and K inputs of the second stage, each time the output of the lowest stage is a 1 the second stage toggles on the next clock pulse.

Finally, the third column (third stage) toggles when both the first stage and the second stage are both 1s (line D). Thus by ANDing the Q outputs of the first two stages, and then connecting them to the J and K inputs of the third stage, the third stage will toggle whenever the first two stages are 1s.

There are formal methods for determining the wiring of synchronous counters. The illustration above is one manual method that may be used to design a counter of this type. The advantage of the synchronous counter is that at any instant, except during clock pulse transition, all counter stage outputs *are correct* and delay due to propagation through the flip flops is not a problem.

In the synchronous counter, Figure 21B, each stage is controlled by a common clock signal.

There are numerous variations on this first example of a counter. Most counters have the ability to *clear* the count to 0. Some counters can also *preset* to a desired count. The clear and preset control inputs are often asynchronous — they change the output state without being clocked. Counters may either count up (increment) or down (decrement). *Up/down* counters can be controlled to count in either direction. Counters can have sequences other than the standard numbers, for example a BCD counter.

Counters are also not restricted to changing state on every clock cycle. An n-bit counter that changes state only after m clock pulses is called a *divider* or *divide-by-m* counter. There are still $2^n$ = m states; however, the output after p clock pulses is now p / m. Combining different divide-by-m counters can result in almost any desired count. For example, a base 12 counter can be made from a divide-by-2 and a divide-by-6 counter; a base 10 (decade) counter consists of a divide-by-2 and a BCD divide-by-5 counter.

The outputs of these counters are binary. To produce output in decimal form, the output of a counter would be provided to a binary-to-decimal decoder chip and/or an LED display.

### REGISTERS

Groups of flip-flops can be combined to make registers, usually implemented with D flip-flops. A *register* stores n bits of information, delivering that information in response to a clock pulse. Registers usually have asynchronous *set* to 1 and *clear* to 0 capabilities.

#### Storage Register

A storage register simply stores temporary information, for example, incoming information or intermediate results. The size is related to the basic size of information handled by a computer: 8 flip-flops for an 8-bit or *byte register* or 16 bits for a *word register*. **Figure 22** shows a typical circuit and schematic symbols for an 8-bit storage register.

#### Shift Register

Shift registers also store information and provide it in response to a clock signal, but they handle their information differently: When a clock pulse occurs, instead of each flip-flop passing its result to the output, the flip-flops pass their data to each other, up and down the row. For example, in up mode, each flip-flop receives the output of the preceding flip-flop. A data bit starting in flip-flop D0 in a left shifter would move to D1, then D2 and so on until it is shifted out of the register. If a 0 was input to the least significant bit, D0, on each clock pulse then, when the last data bit has been shifted out, the register contains all 0s.

Shift registers can be left shifters, right shifters or controlled to shift in either direction. The most general form, a *universal shift register*, has two control inputs for four states: Hold, Shift right, Shift left and Load. Most also have asynchronous inputs for preset, clear and parallel load. The primary use of shift registers is to convert parallel information to serial or vice versa. Additional uses for a shift register are to delay or synchronize data, and to multiply or divide a number by a factor $2^n$. Data can be delayed simply by taking advantage of the Hold feature of the register control inputs. Multiplication and division with shift registers is best explained by example: Suppose a 4-bit shift register currently has the value 1000 = 8. A right shift

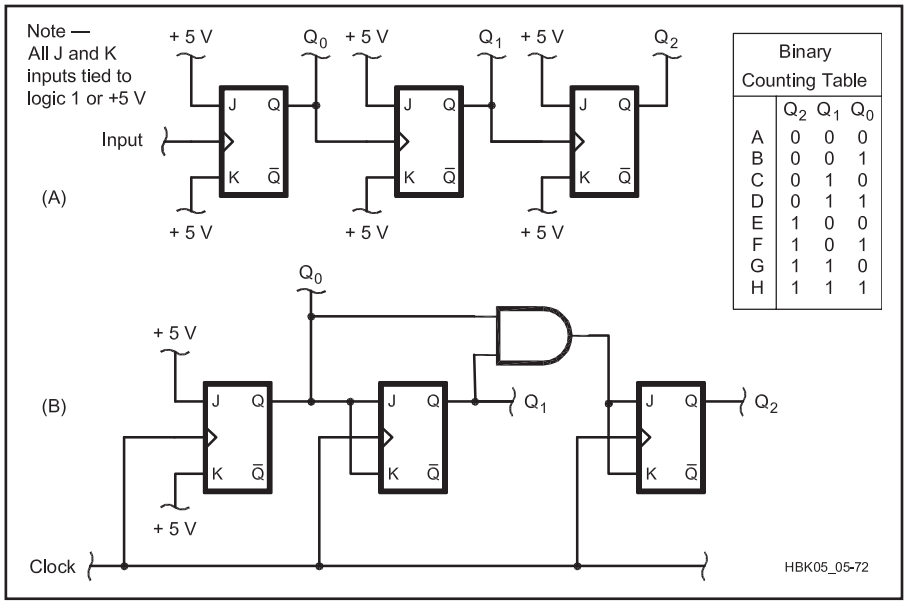

**Figure 21 — Three-bit binary counter using J-K flip-flops: (A) asynchronous or ripple, (B) synchronous.**

results in the new parallel output 0100 = 4 = 8 / 2. A second right shift results in 0010 = 2 = (8 / 2) / 2. Together the 2 right shifts performed a division by $2^2$. In general, shifting right n times is equivalent to dividing by $2^n$. Similarly, shifting left multiplies by $2^n$. This can be useful to compiler writers to make a computer program run faster.

## 5.4 Multivibrators

*Multivibrators* are a general type of circuit with three varieties: bistable, monostable and astable. The only truly digital multivibrator is bistable, having two stable states. The flip-flop is a *bistable multivibrator*: both of its two states are stable; it can be triggered from one stable state to the other by an external signal. The other two varieties of multivibrators are partly analog circuits and partly digital. While their output is one or more pulses, the internal operation is strictly analog.

### MONOSTABLE MULTIVIBRATOR

A *monostable* or *one-shot* multivibrator has one energy-storing element in its feedback paths, resulting in one stable and one quasi-stable state. It can be switched, or *triggered*, to its quasi-stable state; then returns to the stable state after a time delay. Thus, when triggered, the one-shot multivibrator puts out a pulse of some duration, T.

A very common integrated circuit used for non-precision generation of a signal pulse is the 555 timer IC. **Figure 23** shows a 555 connected as a one-shot multivibrator. The one-shot is activated by a negative-going pulse between the trigger input and ground. The trigger pulse causes the output (Q) to go positive and capacitor C to charge through resistor R. When the voltage across C reaches two-thirds of $V_{CC}$, the capacitor is quickly discharged to ground and the output returns to 0. The output remains at logic 1 for a time determined by

$$T = 1.1\ RC$$

where:

R = resistance in ohms, and
C = capacitance in farads.

A very common, but again, non-precision application of this circuit is the generation of a delayed pulse. If there is a requirement to generate a 50 µs pulse, but delayed from a trigger by 20 ms, two 555s might be used. The first 555, configured as an astable multivibrator, generates the 20-ms pulse, and the trailing edge of the 20-ms pulse is used to trigger a second 555 that in turn generates the 10 µs pulse. See the **Circuits and Components** chapter for more information on the 555 timer and related circuits.

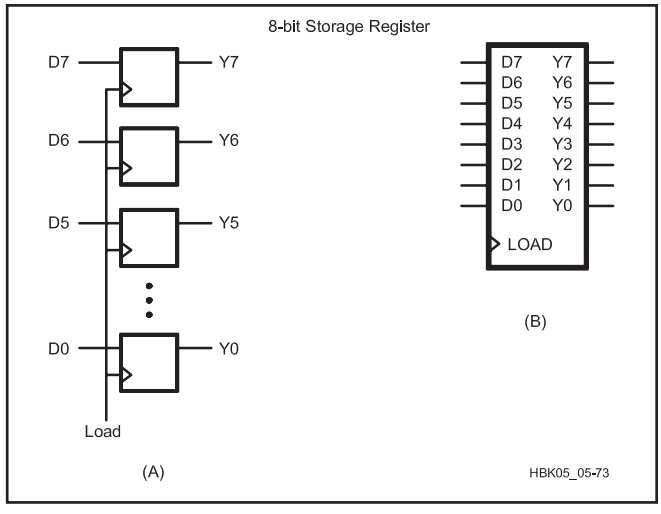

**Figure 22 — An eight-bit storage register: (A) circuit and (B) schematic symbol.**

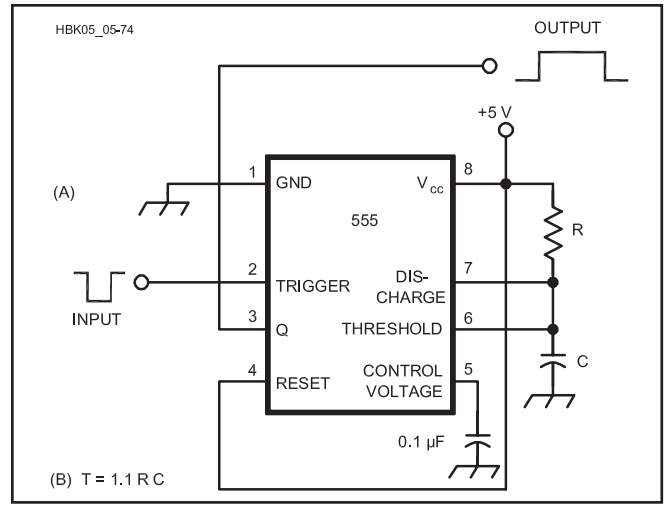

**Figure 23 — (A) A 555 timer connected as a monostable multivibrator. (B) The equation to calculate values where T is the pulse duration in seconds, R is in ohms and C is in farads.**

### ASTABLE MULTIVIBRATOR

An *astable* or *free-running* multivibrator has two energy-storing elements in its feedback paths, resulting in two quasi-stable states. It continuously switches between these two states without external excitation. Thus, the astable multivibrator puts out a sequence of pulses. By properly selecting circuit components, these pulses can be of a desired frequency and width.

**Figure 24** shows a 555 timer IC connected as an astable multivibrator. The capacitor C charges to two-thirds $V_{CC}$ through R1 and R2 and discharges to one-third $V_{CC}$ through R2. The ratio R1 : R2 sets the asserted high duty cycle of the pulse: $t_{HIGH} / t_{PERIOD}$. The output frequency is determined by:

$$f = \frac{1.46}{(R1 + 2\,R2)\,C}$$

where:
R1 and R2 are in ohms,
C is in farads and
f is in hertz.

It may be difficult to produce a 50% duty cycle due to manufacturing tolerance for the resistors R1 and R2. One way to ensure a 50% duty cycle is to run the astable multivibrator at 2f and then divide by 2 with a toggle flip-flop.

Astable multivibrators, and the 555 integrated circuit in particular, are very often used to generate clock pulses. Although this is a very inexpensive and minimum hardware approach, the penalty is stability with temperature. Since the frequency and the pulse dimensions are set by resistors and capacitors, drift with temperature and to some extent aging of components will result in changes with time. This is no different than the problem faced by designers of L-C controlled VFOs.

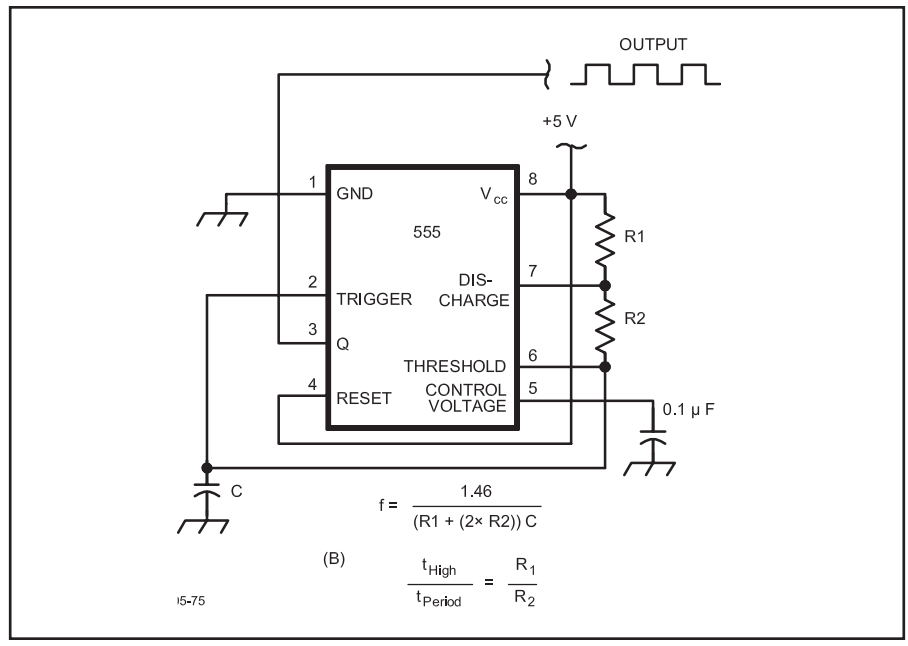

**Figure 24 — (A) A 555 timer connected as an astable multivibrator. (B) The equations to calculate values for R1, R2 in ohms and C in farads, where f is the clock frequency in Hertz.**

# 6 Digital Integrated Circuits

*Integrated circuits* (ICs) are the cornerstone of digital logic devices. Modern technology has enabled electronics to become smaller and smaller in size and less and less expensive. Much of today's complex digital equipment would be impossible to build with discrete transistors and discrete components.

An IC is a miniature electronic module of components and conductors manufactured as a single unit. All you see is a ceramic or black plastic package and the silver-colored pins sticking out. Inside the package is a piece of material, usually silicon, created (fabricated) in such a way that it conducts an electric current to perform logic functions, such as a gate, flip-flop or decoder.

As each generation of ICs surpassed the previous one, they became classified according to the number of gates on a single chip. These classifications are roughly defined as:

Small-scale integration (SSI):
10 or fewer gates on a chip.

Medium-scale integration (MSI):
10-100 gates.

Large-scale integration (LSI):
100-1000 gates.

Very-large-scale integration (VLSI):
1000 or more gates.

Though SSI and MSI logic chips are still useful for building circuits to handle very simple tasks, it is more common to see them either used along with or completely replaced by programmable logic arrays and microcontrollers. In many cases you will see the smaller logic circuits referred to as "glue logic."

## 6.1 Comparing Logic Families

When selecting devices for a circuit, a designer is faced with choosing between many families and subfamilies of logic ICs. The determination of which logic subfamily is right for a specific application is based upon several desirable characteristics: logic speed, power consumption, fan-out, noise immunity and cost. From a practical viewpoint, the primary IC families available and in common use today are CMOS, with TTL a distant second place. Within these families, there are tradeoffs that can be made with respect to individual circuit capabilities, especially in the areas of speed and power consumption. Except under the most de--manding circumstances, normal commercial grade temperature rating will do for amateur

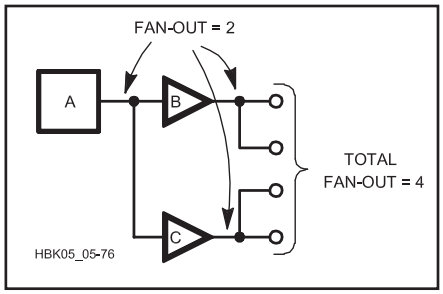

**Figure 25 — Nonverting buffers used to increase fan-out: Gate A (fan-out = 2) is connected to two buffers, B and C, each with a fan-out of 2. Result is a total fan-out of**

service.

### FAN-OUT

Fan-out is a term with which you will need to become familiar when working with TTL logic families such as 7400, 74LS or 74S. A gate output can supply only a limited amount of current. Therefore, a single output can only drive a limited number of inputs. The measure of driving ability is called fan-out, expressed as the number of inputs (of the same subfamily) that can be driven by a single output. If a logic family that is otherwise desirable does not have sufficient fan-out, consider using noninverting buffers to increase fan-out, as shown by **Figure 25**.

Another approach is to use a CMOS logic family. These families typically have output drivers capable of sourcing or sinking 20 to 25 mA, and input current leakage in the microampere range. Thus, fan-out is seldom a problem when using these devices.

### NOISE IMMUNITY

The noise margin was illustrated in Figure 2. The choice of voltage levels for the binary states determines the noise margin. If the gap is too small, a spurious signal can too easily produce the wrong state. Too large a gap, however, produces longer, slower transitions and thus decreased switching speeds.

Circuit impedance also plays a part in noise immunity, particularly if the noise is from external sources such as radio transmitters. At low impedances, more energy is needed to change a given voltage level than at higher impedances.

## 6.2 Bipolar Logic Families

Two broad categories of digital logic ICs are *bipolar* and *metal-oxide semiconductor* (MOS). Numerous manufacturing techniques have been developed to fabricate each type. Each surviving, commercially available family has its particular advantages and disadvantages and has found its own special niche in the market. The designer is cautioned, however, that sometimes this niche is simply the ongoing maintenance of old products. There are still very old logic families available for reasonable prices that would be considered quite obsolete and generally not suitable for new designs.

Bipolar semiconductor ICs usually employ NPN junction transistors. (Bipolar ICs can be manufactured using PNP transistors, but NPN transistors make faster circuits.) While early bipolar logic was faster and had higher power consumption than MOS logic, the speed difference has largely disappeared as manufacturing technology has developed.

There are several families of bipolar logic devices, and within some of these families there are subfamilies. The most-used bipolar logic family is transistor-transistor logic (TTL). Another bipolar logic family, Emitter Coupled Logic (ECL), has exceptionally high speed but high power consumption.

### TRANSISTOR-TRANSISTOR LOGIC (TTL)

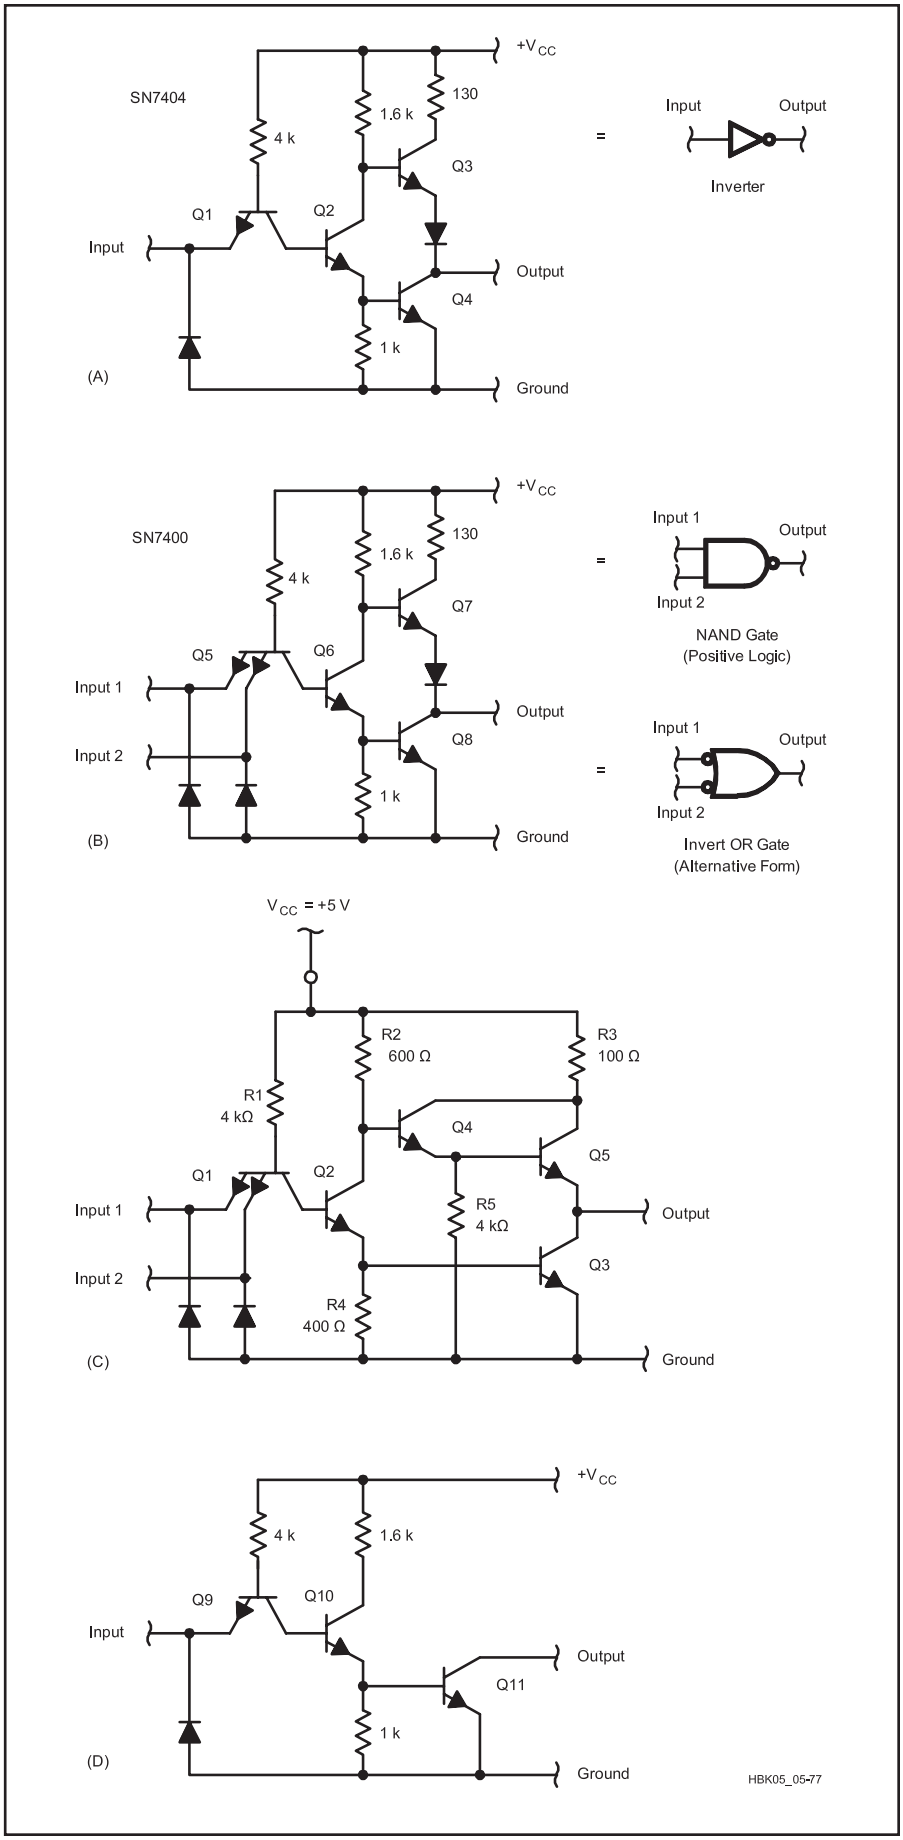
The TTL family saw widespread acceptance through the 1960s, 1970s and 1980s because it was fast compared to early MOS and CMOS logic, and has good noise immunity. It was by far the most commonly used logic family for a couple of decades. Though TTL logic is not in widespread use today for new designs, the device numbering system devised for TTL chips survives to this day for newer technologies. You will also often see TTL, especially the later low power, higher speed TTL subfamilies, in various equipment you may use and repair.

#### TTL Subfamilies

The original standard TTL used bipolar transistors and "totem-pole" outputs (see **Figure 26A** and B), which were a great improvement over the earlier diode-transistor logic (DTL) and resistor-transistor logic (RTL). Still, TTL logic consumed quite a bit of power even at idle, and there were limits on how many inputs could be driven by a single output. Later versions used Schottky diodes to greatly improve switching speed, and reduced power requirements were introduced.

TTL IC identification numbers begin with either 54 or 7 The 54 prefix denotes an extended military temperature range of –55 to 125 °C, while 74 indicates a commercial temperature range of 0 to 70 °C. The next letters, in the middle of the TTL device number, indicate the TTL subfamily. Following the subfamily designation is a 2, 3 or 4-digit device-identification number. For example, a 7400 is a standard TTL NAND gate and a 74LS00 is a low-power Schottky NAND gate (The NAND gate is the workhorse TTL chip). A partial list of TTL subfamilies includes:

| | | |
|---|---|---|
| | 74xx | standard TTL |
| H | 74Hxx | High-speed |
| L | 74Lxx | Low-power |
| S | 74Sxx | Schottky |
| F | 74Fxx | Fairchild Advanced Schottky |
| LS | 74LSxx | Low-power Schottky |
| AS | 74ASxx | Advanced Schottky |
| ALS | 74ALSxx | Advanced Low-power Schottky |



Each subfamily is a compromise between speed and power consumption. **Table 5.9** shows some of these characteristics. Because the speed-power product is approximately constant, less power consumption generally results in lower speed and vice versa. The advanced low power Schottky devices (ALS, F) offer both increased speed and reduced power consumption. Historically, an additional consideration to the speed-versus-power trade-off has been the cost trade-off. For the amateur, this is not nearly the factor it once was as component costs are relatively low for the newer, faster, lower powered parts.

When a TTL gate changes state, the amount of current that it draws changes rapidly. These changes in current, called switching tran-

**Table 9**
**TTL and CMOS Subfamily Performance Characteristics**

| *TTL Family* | *Propagation Delay (ns)* | *Per Gate Power Consumption (mW)* | *Speed Power Product (pico-joules)* |
|---|---|---|---|
| Standard | 9 | 10 | 90 |
| L | 33 | 1 | 33 |
| H | 6 | 22 | 132 |
| S | 3 | 20 | 60 |

| ACT | 75 | 0.080 | 0.755 | 7.505 | 0.4 | 3.6 | 36 |

sients, appear on the power supply line and can cause false triggering of other devices. For this reason, the power bus should be adequately decoupled. For proper decoupling of TTL circuits, connect a 0.01 to 0.1 µF capacitor from $V_{CC}$ to ground near each device to minimize the transient currents caused by device switching and magnetic coupling. These capacitors must be low-inductance, high-frequency RF capacitors (ceramic capacitors are preferred). In addition, a large-value (50 to 100 µF) capacitor should be connected from $V_{CC}$ to ground somewhere on the board to accommodate the continually changing $I_{CC}$ requirements of the total $V_{CC}$ bus line. These are generally low-inductance tantalum capacitors.

## Darlington and Open-Collector Outputs

Figure 26C and D show variations from the totem-pole configuration. They are the Darlington transistor pair and the open-collector configuration respectively.

The Darlington pair configuration replaces the single transistor Q4 with two transistors, Q4 and Q5. The effect is to provide more current-sourcing capability in the high state. This has two benefits: (1) the rise time is decreased and (2) the fan-out is increased.

Transistor(s) on the output in both the totem-pole and Darlington configurations provide active pull-up. Omitting the transistor(s) and providing an external resistor for passive pull-up gives the open-collector configuration. This configuration, unfortunately, results in slower rise time, since a relatively large external resistor must be used. The technique has some very useful applications, however: driving other devices, performing wired logic, busing and interfacing between logic devices.

Devices that need other than a 5-V supply can be driven with the open-collector output by substituting the device for the external resistor. Example devices include LEDs, relays and solenoids. Inductive devices like relay coils and solenoids need a protection diode across the coil. You must pay attention to the current ratings of open-collector outputs in such applications. You may need a switching transistor to drive some relays or other high-current loads.

Open-collector outputs can perform

**Figure 26 — Example TTL circuits and their equivalent logic symbols: (A) an inverter and (B) a NAND gate, both with totem-pole outputs. (C) A NAND gate with a Darlington output. (D) A NAND gate with an open-collector output. (Indicated resistor values are typical. Identification of transistors is for text reference only. These are not discrete components but parts of the silicon die.)**

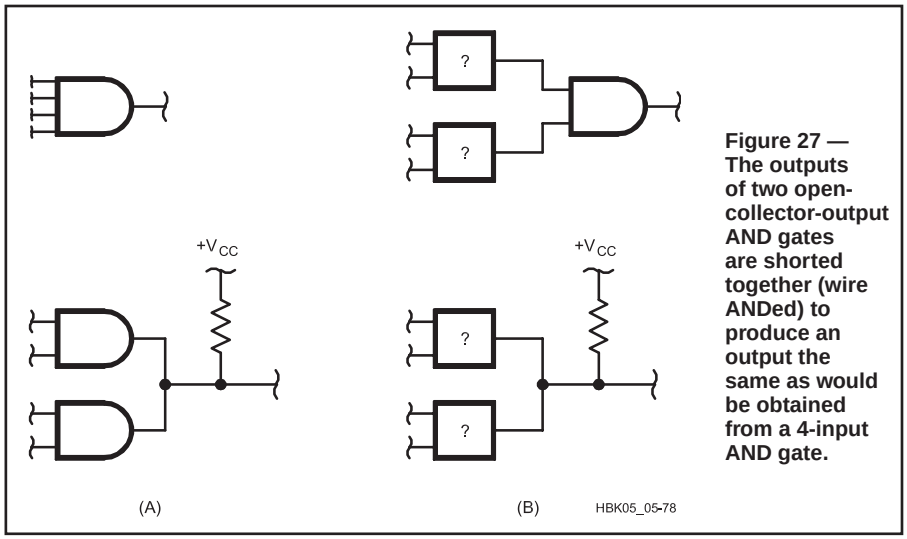

**Figure 27 — The outputs of two open-collector-output AND gates are shorted together (wire ANDed) to produce an output the same as would be obtained from a 4-input AND gate.**

wired logic, rather than gated IC logic, by wire-ANDing the outputs. This can save the designer an AND gate, potentially simplifying the design. Wire-ANDed outputs are several open-collector outputs connected to a single external pull-up resistor. The overall output, then, will only be high when all pull-down transistors are OFF (all connected outputs are high), effectively performing an AND of the connected outputs. If any of the connected outputs are low, the output after the external resistor will be low. **Figure 27** illustrates the wire-ANDing of open-collector outputs.

The wire-ANDed concept can be applied to several devices sharing a common bus. At any time, all but one device has a high-impedance (off) output. The remaining device, enabled with control circuitry, drives the bus output.

Open-collector outputs are also useful for interfacing TTL gates to gates from other logic families. TTL outputs have a minimum high level of 2.4 V and a maximum low level of 0.4 V. When driving non-TTL circuits, a pull-up resistor (typically 2.2 kΩ) connected to the positive supply can raise the high level to 5 V. If a higher output voltage is needed, a pull-up resistor on an open-collector output can be connected to a positive supply greater than 5 V, so long as the chip output voltage and current maximums are not exceeded.

### Three-State Outputs

While open-collector outputs can perform bus sharing, a more popular method is three-state output, or tristate, devices. The three states are low, high and high impedance, also called Hi-Z or *floating*. An output in the high-impedance state behaves as if it is disconnected from the circuit, except for possibly a small leakage current. Three-state devices have an additional disable input. When the enable input is active, the device provides high and low outputs just as it would normally; when enable is inactive, the device goes into its high-impedance state.

A bus is a common set of wires, usually used for data transfer. A three-state bus has several three-state outputs wired together. With control circuitry, all devices on the bus but one have outputs in the high-impedance state. The remaining device is enabled, driving the bus with high and low outputs. Care should be taken to ensure only one of the output devices can be enabled at any time, since simultaneously connected high and low outputs may result in an incorrect logic voltage. (The condition when more than one driver is enabled at the same time is called *bus contention*.) Also, the large current drain from $V_{CC}$ to ground through the high driver to the low driver can potentially damage the circuit or produce noise pulses that can affect overall system behavior.

### Unused TTL Inputs

A design may result in the need for an n-input gate when only an n + m input gate is available. In this case, the recommended solution for extraneous inputs is to give the extra inputs a constant value that won't affect the output. A low input is easily provided by connecting the input to ground. A high input can be provided with either an inverter whose input is ground or with a pull-up resistor. The pull-up resistor is preferred rather than a direct connection to power because the resistor limits the current, thus protecting the circuit from transient voltages. Usually, a 1-kΩ to 5-kΩ resistor is used; a single 1-kΩ resistor can handle up to 10 inputs.

It's important to properly handle all inputs. Design analysis would show that an unconnected, or floating TTL input is usually high but can easily be changed low by only a small amount of capacitively-coupled noise.

## 6.3 Metal Oxide Semiconductor (MOS) Logic Families

While bipolar devices use junction transistors, MOS devices use field effect transistors (FETs). MOS is characterized by simple device structure, small size (high density) and ease of fabrication. MOS circuits use the NOR gate as the workhorse chip rather than the NAND. MOS families, specifically CMOS, are used extensively in most digital devices today because of their low power consumption and high speed.

### P-CHANNEL MOS (PMOS)

The first MOS devices to be fabricated were PMOS, conducting electrical current by the flow of positive charges (holes). PMOS power consumption is much lower than that of bipolar logic, but its operating speed is also lower. The only extensive use of PMOS was in calculators and watches, where low speed is acceptable and low power consumption and low cost are desirable. PMOS was replaced by NMOS, which offered substantially higher switching speeds.

### N-CHANNEL MOS (NMOS)

With improved fabrication technology, NMOS became feasible and provided improved performance and TTL compatibility. The speed of NMOS is at least twice that of PMOS, since electrons rather than holes carry the current. NMOS also has greater gain than PMOS and supports greater packaging density through the use of smaller transistors. NMOS has been almost completely obsoleted by CMOS.

### COMPLEMENTARY MOS (CMOS)

CMOS combines both P-channel and N-channel devices on the same substrate to achieve high noise immunity and low power consumption: less than 1 mW per gate and negligible power during standby. This accounts for the widespread use of CMOS in battery-operated equipment. The high impedance of CMOS gates makes them susceptible to electromagnetic interference, however, particularly if long traces are involved. Consider a trace ¼-wavelength long between input and output. The output is a low-impedance point, hence the trace is effectively grounded at this point. You can get high RF potentials ¼-wavelength away, which disturbs circuit operation.

A notable feature of CMOS devices is that the logic levels swing to within a few millivolts of the supply voltages. The input-switching threshold is approximately one half the supply voltage ($V_{DD} - V_{SS}$). This characteristic contributes to high noise immunity on the input signal or power supply lines. CMOS input-current drive requirements are

minuscule, so the fan-out is great, at least in low-speed systems. For high-speed systems, the input capacitance increases the dynamic power dissipation and limits the fan-out.

### CMOS Subfamilies

There are a large number of CMOS subfamilies available. Like TTL, the original CMOS has largely been replaced by later subfamilies using improved technologies; in turn, these will be replaced with even newer families as technology evolves. The original family, called the 4000 series, has numbers beginning with 40 or 45 followed by two or three numbers to indicate the specific device. 4000B is second generation CMOS. When introduced, this family offered low power consumption but was fairly slow and not easy to interface with TTL.

Later CMOS subfamilies offer improved performance and, in some cases, TTL compatibility. For simplicity, the later subfamilies were given numbers similar to the TTL numbering system, with the same leading numbers, 54 or 74, followed by 1 to 4 letters indicating the subfamily and as many as 5 numbers indicating the specific device. The subfamily letters usually include a "C" to distinguish them as CMOS.

Following is a description of some of the CMOS device families available. As there are a substantial number of families offered by specific manufacturer, and there are new families being introduced frequently, this information is by no means exhaustive. A check of IC suppliers' and manufacturers' Web sites will provide the designer with a complete selection of choices to meet his or her requirements.

| | | |
|---|---|---|
| *4000* | *4071B* | *Standard CMOS* |
| *C* | *74Cxx* | *CMOS versions of TTL* |

Largely obsolete today, devices in the 74C subfamily are pin and functional equivalents of many of the most popular parts in the 7400 TTL family. It may be possible to replace all TTL ICs in a particular circuit with 74C-series CMOS, but this family should not be mixed with TTL in a circuit without careful design considerations. Devices in the C series are typically 50% faster than the 4000 series.

| | | |
|---|---|---|
| *HC* | *74HCxx* | *High-speed CMOS* |

Devices in the 74HC subfamily have speed and drive capabilities similar to Low-power Schottky (LS) TTL but with better noise immunity and greatly reduced power consumption. High-speed refers to faster than the previous CMOS family, the 4000-series.

| | | |
|---|---|---|
| *HCT* | *74HCTxx* | *High-Speed CMOS, TTL compatible* |

Devices in this subfamily were designed to interface TTL to CMOS systems. The HCT inputs recognize TTL levels, while the outputs are CMOS compatible. HCT chips are commonly used as lower powered, drop-in replacements for their pin compatible LS TTL counterparts.

| | | |
|---|---|---|
| *AC* | *74ACxxxxx* | *Advanced CMOS* |

Devices in this family have reduced propagation delays, increased drive capabilities and can operate at higher speeds than standard CMOS. They are comparable to Advanced Low-power Schottky (ALS) TTL devices.

| | | |
|---|---|---|
| *ACT* | *74ACTxxxxx* | *Advanced CMOS, TTL compatible* |

This subfamily combines the improved performance of the AC series with TTL-compatible inputs.

| | | |
|---|---|---|
| *AHCT* | *74AHCTxxxx* | *Advanced High Speed CMOS, TTL Compatible* |

This subfamily is substantially faster than HC and HCT, but only slightly faster than ACT in switching speed. It has lower output drive capacity than AC/ACT.

New CMOS subfamilies are being introduced regularly. The current move is to lower voltage operation; where 5 V was the most common supply voltage until a few years ago, 3.3 V and lower supplies are becoming more common. Many newer microprocessors, microcontrollers and intelligent peripheral chips require 3.3 V logic.

| | | |
|---|---|---|
| *LVC* | *74LVCxxxx* | *Low Voltage CMOS* |

This subfamily uses a 3.3 V supply rather than 5 V. It offers low propagation delay (under 5 ns typical), extremely low supply current, robust output drive capabilities, and 5-V TTL compatible inputs.

| | | |
|---|---|---|
| *ALVC* | *74ALVCxxxx* | *Advanced Low Voltage CMOS* |

Even faster than LVC, this family offers propagation delays if under 3ns. Current demands are slightly higher, but still lower than 5V CMOS.

| | | |
|---|---|---|
| *VCX* | *74VCXxxxx* | *Low voltage CMOS* |

This family operates at supply voltages of 1.8 or 3.6 V. Offering high switching speeds and low propagation delays, it does not have TTL-compatible buffered inputs.

As with TTL, each CMOS subfamily has characteristics that may make it suitable or unsuitable for a particular design. You should consult the manufacturer's data books for complete information on each subfamily being considered.

### CMOS Circuits

A simplified diagram of a CMOS logic inverter is shown in **Figure 28**. When the input is low, the resistance of Q2 is low so a high current flows from $V_{CC}$. Since Q1's resistance is high, Q2 sinks current from the output, pulling it low. When the input is high, the opposite occurs: Q1's resistance is low, Q2's is high and Q1 sources current to the output, driving it high. The diodes are to protect the circuit against static charges.

### Special Considerations

Some of the diodes in the input- and output-protection circuits are an inherent part of the manufacturing process. Even with the protection circuits, however, CMOS ICs are susceptible to damage from static charges. To protect against damage from static, the pins should not be inserted in Styrofoam as is sometimes done with other components. Instead, a spongy conductive foam, usually black or pink in color, is available for this purpose. Before removing a CMOS IC from its protective material, make certain that your body is grounded. Touching nearly any large metal object before handling the ICs is probably adequate to drain any static charge off your body. Some people prefer to touch a grounded metal object or to use a conductive bracelet connected to the ground terminal of a three-wire ac outlet through a 10-MΩ resistor. Since wall outlets aren't always wired properly, you should measure the voltage between the ground terminal and any metal objects you might touch. Connecting yourself to ground through a 1-MΩ to 10-MΩ resistor will limit

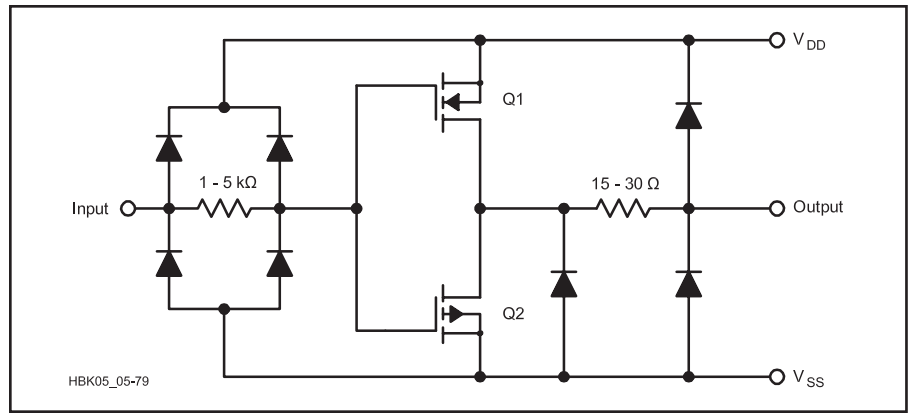

**Figure 28 — Internal structure of a CMOS inverter.**

any current that might flow through your body.

All CMOS inputs should be tied to an input signal. A positive supply voltage or ground is suitable if a constant input is desired. Undetermined CMOS inputs, even on unused gates, may cause gate outputs to oscillate. Oscillating gates draw high current, and may overheat and self destruct.

The low power consumption of CMOS ICs made them attractive for satellite applications, but standard CMOS devices proved to be sensitive to low levels of radiation — cosmic rays, gamma rays and X rays. Later, radiation-hardened CMOS ICs, able to tolerate $10^6$ rads, made them suitable for space applications. (A rad is a unit of measurement for absorbed doses of ionizing radiation, equivalent to $10^{-2}$ joules per kilogram.)

### SUMMARY

There are many types of logic ICs, each with its own advantages and disadvantages. Regardless of the application, consult up-to-date product specification sheets and manufacturer literature when designing logic circuits. IC data sheets, application notes, databooks and more are available from IC manufacturers via their Web sites. By using a search engine and entering a few key word specifications, you will locate application notes, tutorials and a host of other information.

## 6.4 Interfacing Logic Families

Each semiconductor logic family has its own advantages in particular applications. When a design mixes ICs from different logic families, the designer must account for the differing voltage and current requirements each logic family recognizes. The designer must ensure the appropriate interface exists between the point at which one logic family ends and another begins. Knowledge of the specific input/output (I/O) characteristics of each device is necessary, and knowledge of the general internal structure is desirable to ensure reliable digital interfaces. Typical internal structures have been illustrated for each common logic family. **Figure 29** illustrates the logic level changes for different TTL and CMOS families. Data sheets should be consulted for manufacturer's specifications.

Often more than one conversion scheme is possible, depending on whether the designer wishes to optimize power consumption or speed. Usually one quality must be traded off for the other. The following section discusses some specific logic conversions. Where an electrical connection between two logic systems isn't possible, an optoisolator can sometimes be used.

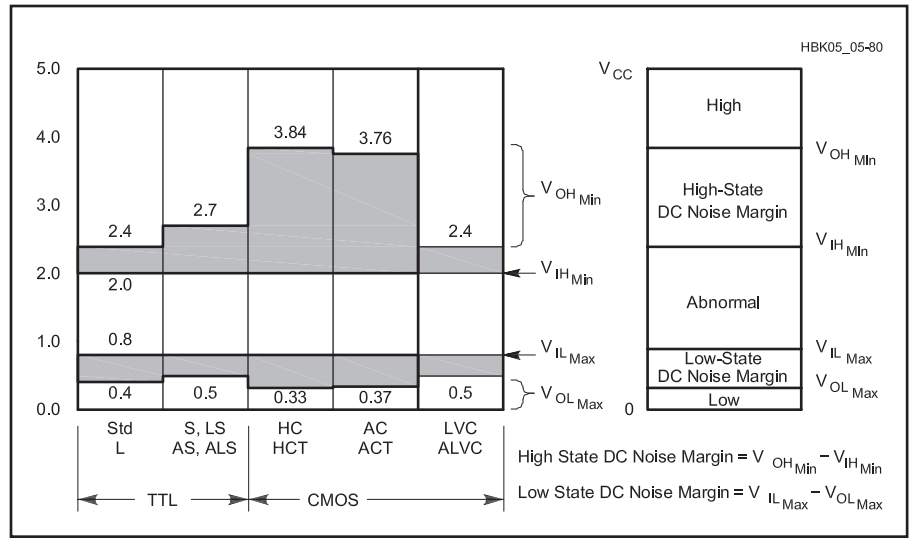

**Figure 29 — Differences in logic levels for some TTL and CMOS families.**

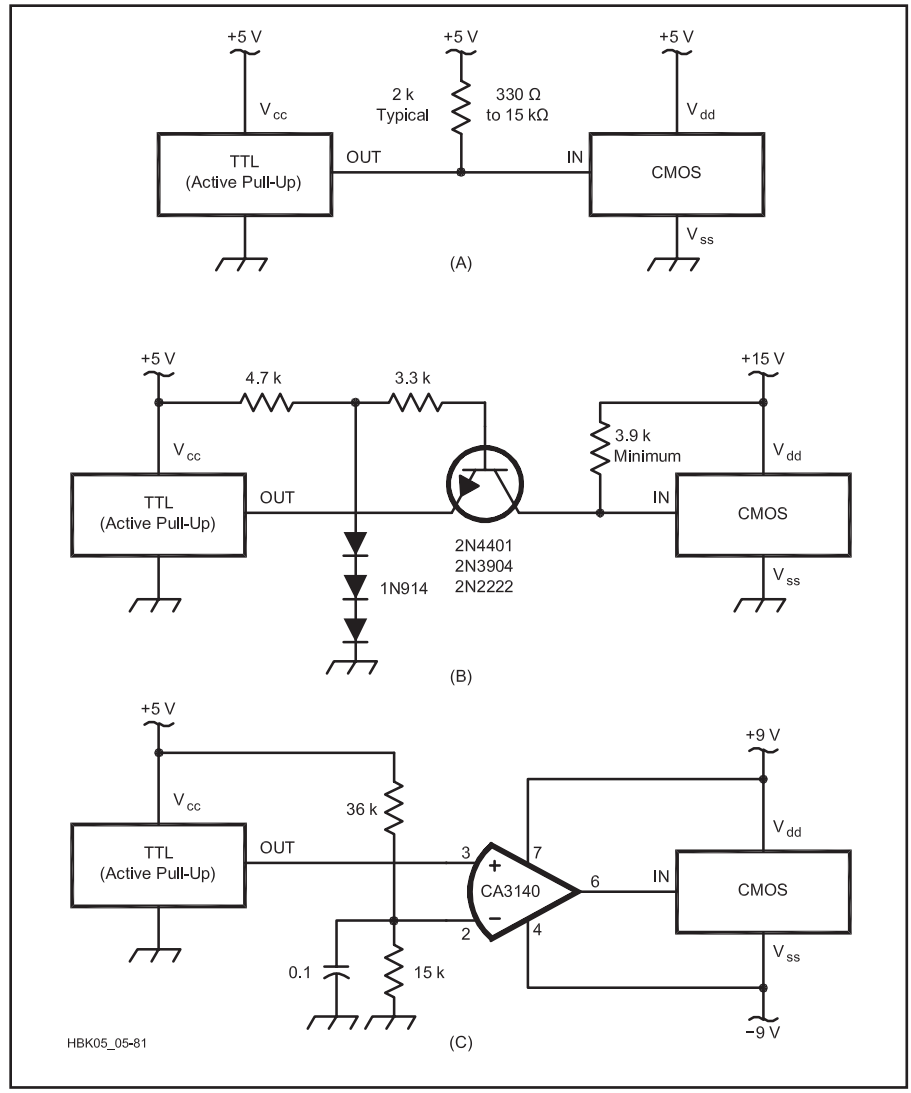

**Figure 30 — TTL to CMOS interface circuits: (A) pull-up resistor, (B) common-base level shifter and (C) op amp configured as a comparator.**

### TTL DRIVING CMOS

TTL and low-power TTL can drive 74C series CMOS directly over the commercial temperature range without an external pull-up resistor. However, they cannot drive 4000-series CMOS directly, and for HC-series devices, a pull-up resistor is recommended. The pull-up resistor, connected between the output of the TTL gate and $V_{CC}$ as shown in **Figure 30A**, ensures proper operation and enough noise margin by making the high output equal to $V_{DD}$. Since the low output voltage will also be affected, the resistor value must be chosen with both desired high and low voltage ranges in mind. Resistor values in the range 1.5 kΩ to 7 kΩ should be suitable for all TTL families under worst conditions. A larger resistance reduces the maximum possible speed of the CMOS gate; a lower resistance generates a more favorable RC product but at the expense of increased power dissipation.

HCT-series and ACT-series CMOS devices were specifically designed to interface non-CMOS devices to a CMOS system. An HCT device acts as a simple buffer between the non-CMOS (usually TTL) and CMOS device and may be combined with a logic function if a suitable HCT device is available.

When the CMOS device is operating from a power supply other than +5 V, the TTL interface is more complex. One fairly simple technique uses a TTL open-collector output connected to the CMOS input, with a pull-up resistor from the CMOS input to the CMOS power supply. Another method, shown in Figure 30B, is a common-base level shifter. The level shifter translates a TTL output signal to a +15 V CMOS signal while preserving the full noise immunity of both gates. An excellent converter from TTL to CMOS using dual power supplies is to configure an operational amplifier as a comparator, as shown in Figure 30C. An FET op amp is shown because its output voltage can usually swing closer to the rails (+ and – supply voltages) than a bipolar device.

### CMOS DRIVING TTL

Certain CMOS devices (including most modern 5 V powered CMOS logic families) can drive TTL loads directly. The output voltages of CMOS are compatible with the input requirements of TTL, but the input-current requirement of TTL limits the number of TTL loads that a CMOS device can drive from a single output (the fan-out).

Interfacing CMOS to TTL is a bit more complicated when the CMOS is operating at a voltage other than +5 V. One technique is shown in **Figure 31A**. The diode blocks the high voltage from the CMOS gate when it is in the high output state. A germanium diode is preferred because its lower forward-voltage drop provides higher noise immunity

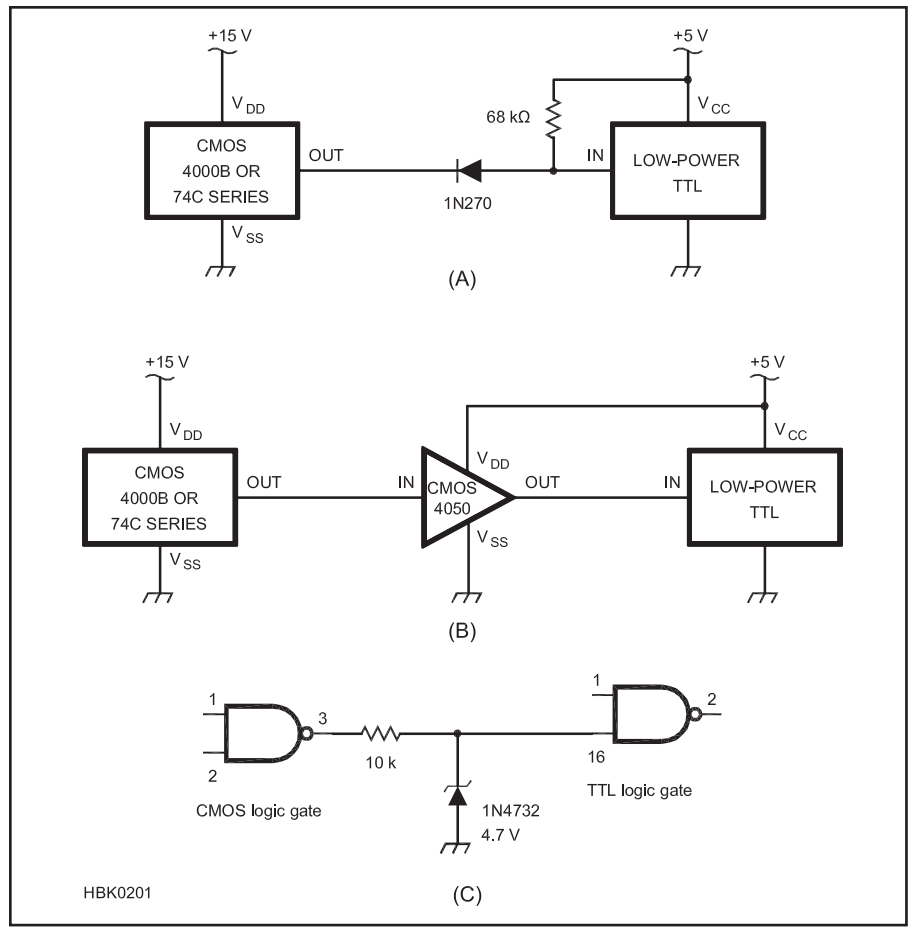

**Figure 31 — CMOS to TTL interface circuits. (A) blocking diode chosen when different supply voltages are used. The diode is not necessary if both devices operate with a +5 V supply. (B) CMOS noninverting buffer IC. (C) Resistor/Zener circuit clamps the voltage to the TTL input at 7 V.**

for the TTL device in the low state. The 68-kΩ resistor pulls the input high when the diode is reverse biased.

A simple resistor/Zener circuit, shown in Fig. 31C, can also be used. This clamps the voltage to the TTL input at 7 V.

There are two CMOS devices specifically designed to interface CMOS to TTL when TTL is using a lower supply voltage. The CD4050 is a noninverting buffer that allows its input high voltage to exceed the supply voltage. This capability allows the CD4050 to be connected directly between the CMOS and TTL devices, as shown in Figure 31B. The CD4049 is an inverting buffer that has the same capabilities as the CD4050.

### 5 V DRIVING 3.3 V LOGIC

Low voltage logic operating with 3.3 to 3.6 V supplies is becoming more and more common. Some of these logic families have 5 V tolerant inputs and can be driven directly by TTL levels; others require buffering to keep inputs at or below the supply voltage. Output levels may or may not be sufficient to drive TTL level inputs reliably under all conditions. The use of TTL compatible buffers (74LVC, 74ALVC) on input signals is a safe way to drive these devices. Since the low logic voltages are compatible, a simple Zener clamp arrangement may also be sufficient.

### 3.3 V DRIVING 5 V LOGIC

Output voltages of most 3.3 V logic families are sufficient to drive the inputs of TTL-level devices. In some cases, the high level output voltage of a 3.3 V powered device may approach the lower end of the TTL level device's input range. In these cases, a pull-up resistor to 3.3 V will usually be sufficient. It is also possible to use an IC or transistor buffer.

## 6.5 Programmable Logic

As digital logic designs became more and more complex, the size and power consumption of their implementations grew. PLDs (*Programmable Logic Devices*) were introduced to allow the designer to produce application-specific logic without the expense and delay of fabricating custom chips. As explained earlier, the design of a logic circuit

begins with a description; this description is used to determine an equation; then the equation is expanded to components. With programmable logic we can shortcut this process by implementing the equations themselves, programming them into a generic array of gates.

Several families of programmable logic devices have been introduced over the years. The earliest were Programmable Array Logic (PAL) chips, consisting of an array of gates whose inputs, interconnections and outputs could be configured by blowing internal fuses according to a specific design. PALs were followed by Generic Array Logic (GALs), which have more gates and more flexible I/O pin logic. GALs are also erasable and reprogrammable.

Later developments led to the Field Programmable Gate Array (FPGA) and other programmable logic arrays. These devices can contain anywhere from several hundred to millions of logic gates, and up to more than a thousand I/O pins. The connections between gates, and thus the device's function, is determined by complex program code. PLDs can be made to replace large numbers of individual SSI, MSI and even LSI chips, up to and including entire microprocessor cores.

# 7 Analog-Digital Interfacing

Quite often, logic circuits must either drive or be driven from non-logic sources. A very common requirement is sensing the presence or absence of a high (as compared to +5 V) voltage or perhaps turning on or off a 120 V ac device or moving the motor in an antenna rotator. A similar problem occurs when two different units in the shack must be interfaced because induced ac voltages or ground loops can cause problems with the desired signals.

A slow speed but safe way to interface such circuits is to use a relay. This provides absolute isolation between the logic circuits and the load. **Figure 32A** shows the correct way to provide this connection. The relay coil is selected to draw less than the available current from the driving logic circuit. The diode, most often a 1N914 or equivalent switching diode, prevents the inductive load from back-biasing the logic circuit and possibly destroying it.

It is often not possible to find a relay that meets the load requirements *and* has a coil that can be driven directly from the logic output. Figure 32B shows two methods of using transistors to allow the use of higher power relays with logic gates.

Electro-optical couplers such as opto-isolators and solid state relays can also be used for this circuit interfacing. Figure 32C uses an optoisolator to interface two sets of logic circuits that must be kept electrically isolated, and Figure 32D uses a solid state relay to control an ac line supply to a high current load. Note that this example uses a solid state relay with internal current limiting on the input side; the LED input has an impedance of approximately 300 Ω. Some devices may need a series resistor to set the LED current; always consult the device data sheet to avoid exceeding device limits of the relay or the processor's I/O pin. See the **Circuits and Components** chapter for more information on optiosolators.

For safely using signals with voltages higher than logic levels as inputs, the same simple resistor and Zener diode circuit similar to that

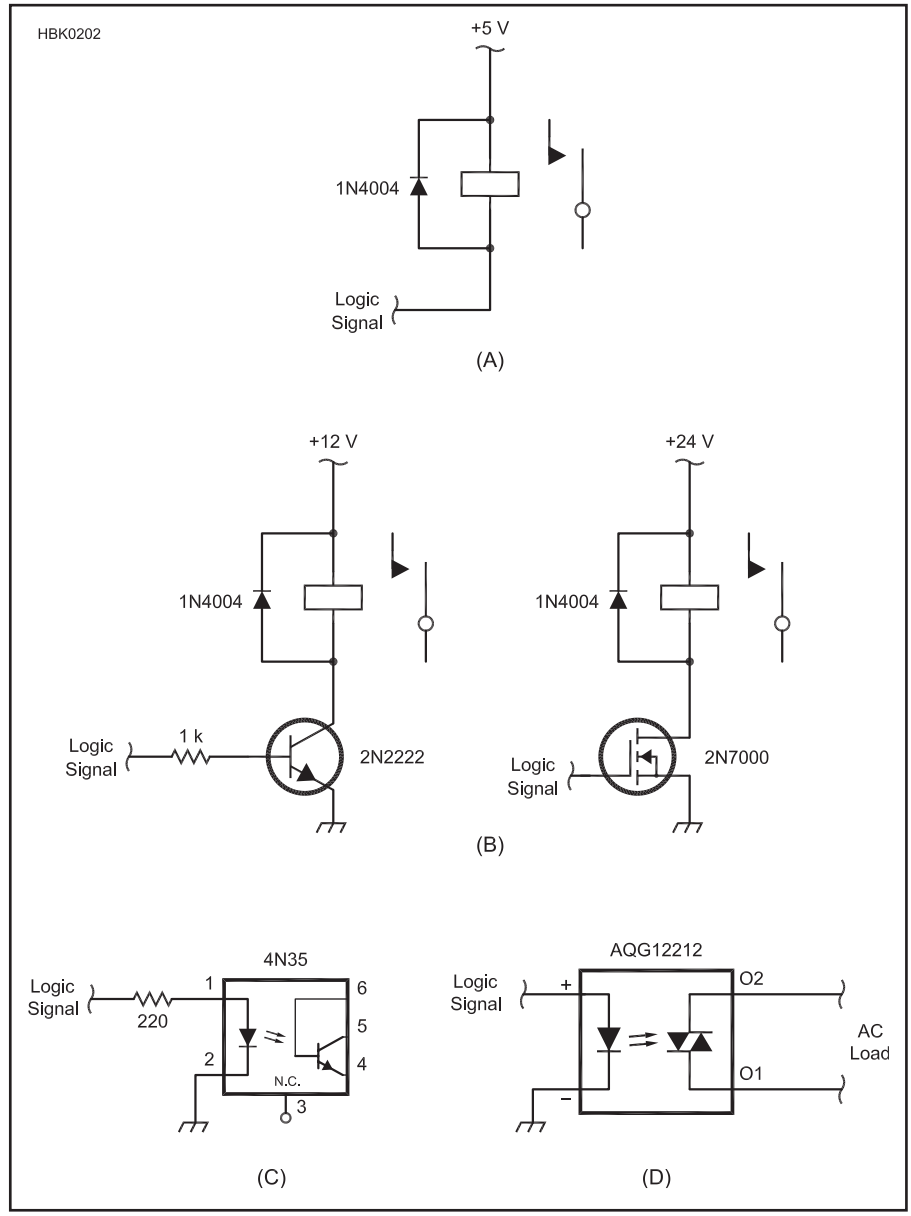

**Figure 32— Interface circuits for logic driving real-world loads. (A) driving a relay from a logic output; (B) using a bipolar transistor or MOSFET to boost current capacity; (C) using an optoisolator for electrical isolation; (D) using a solid-state relay for switching ac loads.**

shown in Figure 31C can be used to clamp the input voltage to an acceptable level. Care must be used to choose a resistor value that will not load the input signal unacceptably.

## 7.1 Analog-Digital Converters

Of course not all signals in the real world are digital. It is often desirable to know the exact voltage of an analog sensor, for example, or to measure the level of something — light, water, current or some other input. Similarly, an analog output can be quite useful for controlling or indicating things that are better left in the analog domain. For this reason we have two types of converters. The analog-to-digital converter (ADC) and digital-to-analog converter (DAC) handle these tasks for us, and they are often fairly easy to use. Additional information on ADCs and DACs may be found in the **Circuits and Components** chapter.

### ADC AND DAC DIGITAL INTERFACES

Interfaces for ADC and DAC chips are generally classed as serial or parallel. Serial interfaces can vary in speed, complexity and the number of wires required for operation. A serial interface has the advantage of requiring a small number of processor I/O pins to accommodate data of any length. Whether your ADC is providing 8, 10 or 12 bits, the same small number of I/O signals are used. Some of the most common serial interfaces used for ADC and DAC chips are as follows:

*Serial Peripheral Interconnect (SPI).* This four-wire, synchronous bus and protocol use a common CLK signal, plus data lines for master-to-slave (Master Out-Slave In, or MOSI) and slave-to-master (Master In-Slave Out, or MISO). Multiple devices can be used by providing each with its own Slave Select (SS) signal. Speeds can range up to 70 Mbit/s, depending on the capabilities of the master and slave devices.

*Microwire.* This earlier predecessor to SPI implements a half-duplex subset of SPI using the same signals.

*Inter-IC Communication (I2C) bus.* Originally developed by Philips, this synchronous two-wire bus and protocol use a pair of open-drain lines, Serial Clock (SCL) and Serial Data (SDA). Communication is controlled by a master node, though there may be more than one master attached to the bus. Many peripheral devices can be attached to an I2C bus; a device address is sent by the master to initiate communication with a slave. Speeds range from 10 kbit/s (low speed) to 100 kbit/s (standard) to 400 kbit/s (high speed) and higher.

Parallel interfaces generally have eight or more data lines, plus a chip select, read/write and interrupt controls. The read and write signals may be separate, or may be a single read/write signal — low for WR, and high for RD, for example, or vice versa. The interrupt signal can be used to indicate the end of a conversion cycle to the CPU. In this way the processor can tell the converter to start a conversion, then continue processing until the conversion is complete. This can allow more processing to be done without waiting idly for the ADC or DAC to complete its conversion.

### PROGRAMMING AND COMMUNICATION

Many ADC chips have multiplexed inputs that allow you to use one chip to sample and digitize more than one analog input. In these devices, there is a single converter but several inputs that can be internally switched. Additionally, it is common to be able to program the inputs as single-ended or differential. In the case of the popular ADC0832, for example, you can use its two analog input pins as two separate inputs, or as a single differential input. The ADC0838 expands this to eight single-ended or four differential inputs. In the case of the ADC0832, modes can be mixed. This allows the use of various combinations of single-ended and differential inputs, as needed.

Programming and selecting the inputs is done by sending a series of bits from the processor to the ADC at the beginning of the conversion cycle. **Figure 33** shows a diagram of the signal timing used with the ADC0834 ADC. In the case of the ADC0834, a series of four bits are sent by the CPU to the ADC to select single ended or differential mode, the polarity of the input, and which of the four inputs (or two input pairs) is to be selected. Immediately following the fourth bit, the ADC starts its conversion and starts sending the resulting data to the CPU. Other chips in this family and many from different manufacturers use a similar scheme; the number of program bits sent by the CPU depends on the number of inputs present.

Some chips are also configurable for data format as well. For example, a 12 bit ADC

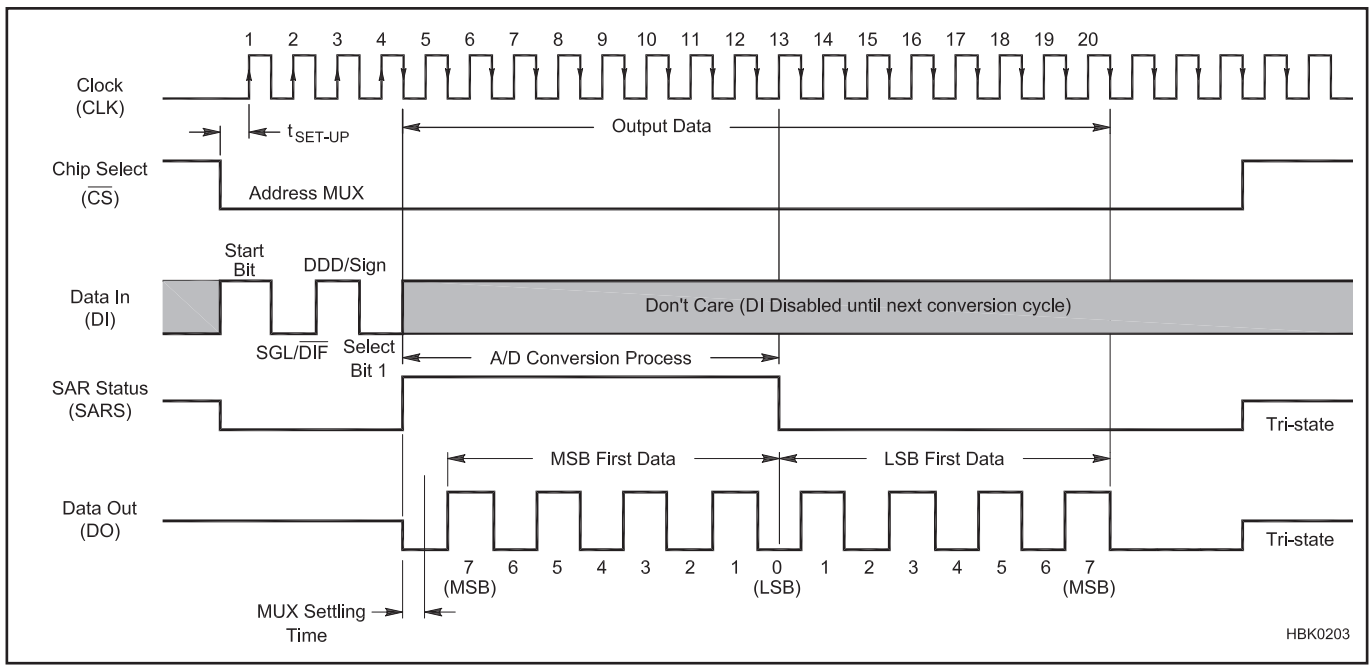

**Figure 33 — ADC0834 timing diagram. Much more information about this device is available from the National Semiconductor datasheet.**

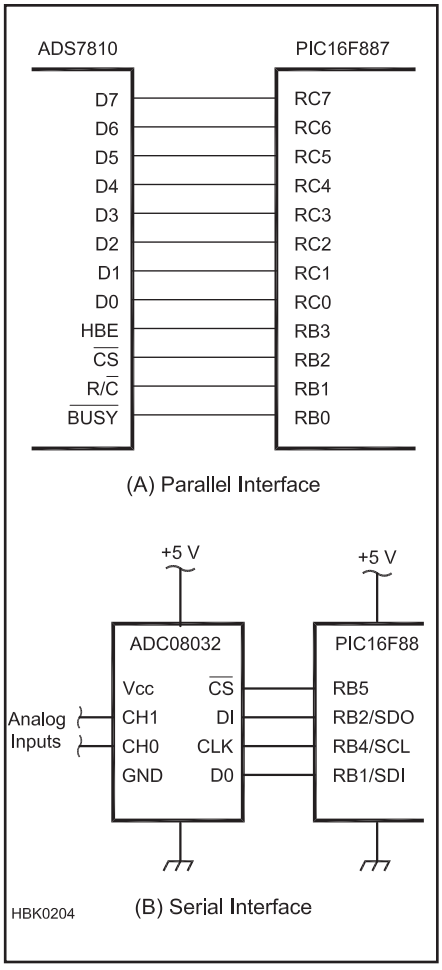

**Figure 34 — A/D converter to microcontroller interfacing: (A) parallel; (B) serial.**

may be programmable to send a sign bit for a total of 13 data bits rather than 12. Data may also be sent LSB first or MSB first. Some chips are configurable for either parallel or serial data transfer; this selection is generally made by pulling a pin or pins high or low to select the mode. In all cases, a careful reading of the device data sheet is your best bet for successful integration of the converter into your project.

## INTERFACING TO YOUR MICROCONTROLLER

Probably the simplest way to interface an external ADC to your microcontroller is by using a parallel interface. In this case, one simply manipulates the I/O pins from the CPU to start the conversion, then reads the resulting data from the data lines. This method is often less desirable than a serial connection, though, due to the limited number of I/O pins usually available. **Figure 34A** shows an example of a parallel interface between a 12 bit ADC (the ADS7810) and a PIC microcontroller (the PIC16F887). In this example, only eight data lines are used for twelve data bits. The HBE signal is used to gate the four high order bits onto the data lines after the low order bits have been read. This saves four I/O pins on the microcontroller.

Serial connections save I/O pins, allow the use of physically smaller IC packages, and can be quite easy to implement. Figure 34B shows an example of a serial interface. If your CPU has a hardware SPI/Microwire interface built in, communication with the ADC can be quite simple from a program standpoint. Simply send the program word, if required, and read the resulting data — either one or two bytes, depending on the ADC resolution. If you do not have built-in hardware SPI, the program code to "bit-bang" the interface is fairly simple to implement. (See **www.dlpdesign.com/images/bit-bang-usb.pdf** for more information on bit-bang.)

Note that Figure 34B shows separate grounds for the processor and ADC. This is required to keep switching noise and transients from affecting the accuracy of readings. A separate analog supply is also recommended. The analog supply should be well filtered using a combination of smaller ceramic or monolithic, and bulk tantalum or other low-ESR capacitors. This should be done for the analog supply and reference voltage supplies. The more noise you can eliminate from the analog supply, the more reliable your readings will be.

## MICROCONTROLLERS WITH BUILT-IN CONVERTERS

It is not at all unusual to find microcontrollers with built-in analog-to-digital converters, complete with multiplexers, analog supply pins and $V_{REF}$ inputs. For example, many Microchip PIC processors are equipped with 10 bit ADCs, and have 5, 8 or more pins that can be configured as multiplexed analog inputs. A few also have digital-to-analog, though this is not nearly as common. While these devices can be extremely useful, there are some limitations. Reference voltages are generally limited to the device's supply voltage. Internal CPU-generated noise may also somewhat limit the usefulness of the converter. With careful attention to device specifications and limitations, though, a built-in ADC may meet the needs of a wide range of uses.

# 8 Microcontroller Overview

This section surveys microcontroller characteristics and applications as they pertain to typical Amateur Radio projects and equipment. The reader interested in using microcontrollers is directed to the many books and Internet resources that exist for learning how to apply microcontrollers. Manufacturer websites such as Microchip (**www.microchip.com**), Freescale (**www.freescale.com**) and Atmel (**www.atmel.com**) are a good place to start. There are also a number of message boards, forums and email lists devoted to specific processor families, such as the PICList (**www.piclist.com**) or the Arduino User Forum (**http://arduino.cc/forum**). Local users groups are often active in large cities. Online communities of microprocessor users are very fluid — use Internet search engines to find current resources.

## 8.1 Selecting a Microcontroller

There are a number of microcontroller families available from several manufactures, each with its own advantages and disadvantages. At the time of this writing, the more popular options for amateur use come from Microchip (PIC product line), Atmel (AVR, ATMega, 8051 and other product lines), Freescale (68HC11, HC08, HC16 and other product lines), and many manufacturers who are building chips based on the venerable Intel 8051 architecture. In addition to these you will see and hear of the Texas Instruments MSP430, ARM, and many others.

Designing projects using microcontrollers can range from relatively simple to quite complex. On the simpler end of the scale are several products intended to bring microcontroller based design ability to people who would otherwise not be able to use these devices. Various breadboard kits and development systems are available to simplify hardware development and program downloading. The following three systems are particular popular:

- Arduino (**www.arduino.cc**) — based on an AVR microcontroller, Arduino boards are available with a variety of capabilities and interfaces. Add-on modules called "shields" are added to interfaces provided on the Arduino board. Software is written in C or C++ and downloaded to the microcontroller. The manufacturer provides free development software.
- Parallax BASIC Stamp (**www.parallax.com**) — a single-board system containing a PIC microcontroller preloaded with PBASIC. Software is written in an editor program on the PC and then downloaded.
- PICAXE — a variety of PIC microcontroller with a special form of BASIC. Various sizes of microcontrollers are available with different numbers of I/O pins and clock speeds. The user is responsible for building the circuit board that supports the microcontroller.

In each of these cases, the user does not necessarily need to have a deep understanding of the details of the microcontroller or its operation. The circuit can be designed with attention paid to keeping signal levels within the limits of the device. Then, one simply writes a program to perform the functions required. To be sure, there are trade-offs. The built-in firmware required to allow the user to write a program may be in a simple language such as BASIC that takes up space and processor cycles, so execution speed is not as fast and programs are somewhat limited.

The BASIC Stamp and PICAXE use specific variants of the PIC microcontroller, so if you need features that are not present in those chips you will need to take a different approach. Still, these can be extremely valuable tools that the average amateur can use with very little time and money invested.

There is a very broad range of microcontrollers available to meet nearly any need. Available devices include 8 bit, 16 bit and 32 bit processors with internal program memory ranging from 512 words up to 256 kbytes and more. At the low end are very low cost, physically small devices (down to 8 pin ICs) that can perform relatively simple tasks with ease. Larger, faster processors may include more memory, more I/O pins, and specialized peripherals. Some of the more common features are ADCs, DACs, pulse width modulation (PWM) outputs, USB interface hardware or digital signal processing.

### I/O REQUIREMENTS

Selecting a microcontroller for a new project involves evaluating your requirements and prior experience. First, evaluate the number of inputs and outputs you are likely to need. If, for example, you need to sample an analog voltage and two switch closures and generate a serial data stream, you will need one analog input and three or more digital I/O pins. Depending on memory requirements, even some of the smallest devices will fit the bill. For a more elaborate design, you may need to scan a 4×4 key switch matrix, drive an LCD module with a parallel interface, control a number of LEDs and interface to a PC through a USB port. In this case, the number of I/O pins needed will eliminate a large number of devices from consideration.

### CPU SIZE, PERFORMANCE AND MEMORY

If you are a computer user, you are used to seeing 32 bit and 64 bit microprocessors, many with more than one CPU core on the same chip. In the world of embedded microcontrollers, things are a little different. Instead of handling an operating system and a large number of different programs, the microcontroller only has to execute one program and is completely dedicated to that task. Unless you require very high speed I/O, need very intensive processing or will be using DSP, a simple 8 bit processor may be more than sufficient. There are dozens of ham related products that use embedded controllers — iambic keyers, APRS transponders, repeater controllers, antenna rotator controls and many other accessories that all use simple 8 bit processors with surprisingly small amounts of program memory. On the other hand, if you are designing a new rig or antenna tuner that will require DSP, chances are you may need a more robust processor.

If you are unsure of what your project will require, you may want to pick a processor family that has scalable, pin-compatible members. For example, Microchip offers processors ranging from 8 bit and 5 million instructions per second (MIPS) with 7 kbytes of program memory, to 16 bit with 48 kbytes of program memory at 30 MIPS. All are pin-compatible, so if you find you need more speed, more memory or more built-in peripherals, you can drop in a different processor without changing the hardware.

Also take into account the physical packaging. Some products are available in through-hole, dual inline (DIP) packages; others are available only in surface mount versions. This can make a difference if you lack the equipment, expertise or desire to work with surface mount components.

### SPECIALIZED PERIPHERALS

Will you need a USB interface? Analog inputs? DSP? Precision timekeeping? It may be easier to select a processor that has the features you need built in. On the other hand, it is relatively easy to add an external real-time clock, ADC or DAC, and it takes only a few I/O pins. There are several USB interface chips available that will handle communication with your PC, and present an asynchronous serial data interface to the microcontroller. This can save a lot of firmware development time and frustration.

### HARDWARE COST AND DEVELOPMENT TOOLS

The cost of the actual microcontroller may be a factor, or it may not. If you are building a

one-off project for your own use, there is not much difference between using a $3 chip and a $30 chip with a built-in BASIC interpreter. The difference in time and effort to develop the firmware may make it well worth the extra money for the easier-to-use solution. If you plan to manufacture your device for a larger audience, the cost difference may lead you to make a different choice.

Take into account the cost of the software and hardware tools needed for development. Does the manufacturer offer a free set of firmware development tools, or will you have to spend extra money for an assembler or compiler? Is there a low cost development kit available with the PC interface you need? Does the device require a simple PC interface to program, or a more expensive dedicated programmer? Do you have any previous experience with the processor family, or will it be a completely new effort for you?

# 9 Personal Computer Interfaces

This section provides an overview of the personal computer (PC) digital interfaces used in the amateur station. Detailed information on using these interfaces is available online, especially in users groups and specialized forums for specific software and hardware applications. This book's chapters on **DSP and SDR Fundamentals**, **Digital Modes and Protocols**, and the online supplement on Digital Communications provide more information on specific applications and techniques. The **Station Accessories** chapter includes PC interface construction projects, as well.

## 9.1 Parallel vs Serial Signaling

To communicate a word to someone across the room, you could hold up flash cards displaying the letters of the word. If you hold up four flash cards, each with a letter on it, all at once, then you are transmitting in parallel. If, instead, you hold up each of the flashcards one at a time, then you are transmitting in serial. *Parallel* means all the bits in a group are handled exactly at the same time. *Serial* means each of the bits is sent in turn over a single channel or wire, according to an agreed sequence. **Figure 35** illustrates parallel and serial signaling.

Both parallel and serial signaling are appropriate for certain circumstances. Parallel signaling is faster, since all bits are transmitted simultaneously, but each bit needs its own conductor, which can be expensive. Parallel signaling is more likely to be used for internal communications. For spanning longer distances, such as to an external device, serial signaling is more appropriate. Each bit is sent in turn, so communication is slower, but it also is less expensive, since fewer channels are needed between the devices.

Most amateur digital communications use serial transmission to minimize cost and complexity. The number of channels needed for signaling also depends on the operational mode. One channel is required per bit for simplex (one-way, from sender to receiver only) and for half-duplex (two-way communication, but only one person can talk at a time), but two channels per bit are needed for full-duplex (simultaneous communications in both directions).

### PARALLEL I/O INTERFACING

**Figure 36** shows an example of a parallel input/output interface, similar to the parallel printer ports once common in PCs. Typically, they have eight data lines and one or more handshaking lines. *Handshaking* involves a number of functions to coordinate the data transfer. For example, the READY line indicates that data are available on all eight data lines. If only the READY line is used, however, the receiver may not be able to keep up with the data. Thus, the STROBE line is added so the receiver can determine when the transmitter is ready for the next character.

Interfacing to the parallel port is very simple and can be done in many languages and under many operating systems. It is an easy way to get a PC to act as a controller in the shack and around the home, with from 8 to 12 independent input or output wires. You can get an old computer either virtually free or for just a few dollars and use it exclusively as a controller. (New computers usually do not have a parallel port.)

By searching the Internet for a combination of "parallel port interface" and the language of your choice (for example, Visual BASIC or C), you can find detailed interfacing and programming instructions. It is a good and relatively simple place to "roll your own," compared to the protocol requirements of interfacing with the serial port or USB.

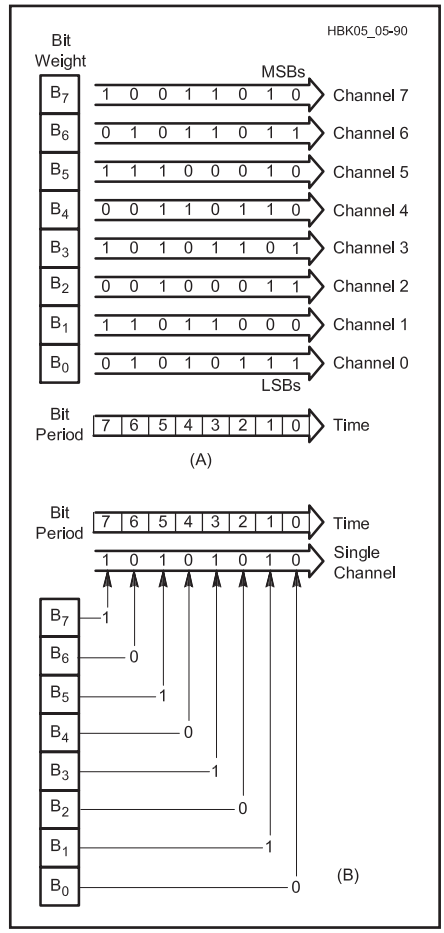

**Figure 35 — Parallel (A) and serial (B) signaling. Parallel signaling in this example uses 8 channels and is capable of transferring 8 bits per bit period. Serial transfer only uses 1 channel and can send only 1 bit per bit period.**

### SERIAL I/O INTERFACING

Serial input/output interfacing is more complex than parallel, since the data must be transmitted based on an agreed sequence. For example, transmitting the 8 bits (b7, b6, . . . b0) of a word includes specifying whether the least significant bit, b0, or the most significant

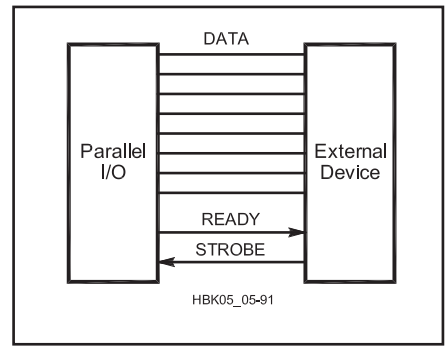

**Figure 36 — Parallel interface with READY and STROBE handshaking lines.**

bit, b7, is sent first. Fortunately, a number of standards have been developed to define the agreed sequence, or encoding scheme.

In order to use a serial interface between a computer and a serial device such as a modem, printer or a new transceiver, several things must be set the same on both ends of the connection. The first is the data rate, the choices for which are usually limited to specific values between 300 and 115200 bits per second for historical reasons. The next is the data format — 7 or 8 bits, and with even, odd or no parity. Finally, both devices must be using the same handshaking method. The usual choices are RTS/CTS, DSR/DTR, or XON/XOFF. The first two use extra signals (and therefore extra wires) to indicate when the transmitting device has data to send, and when the receiving device is able to accept data. In the third method, XON/XOFF, the device receiving data will send an XOFF control character to the transmitting device to indicate that it can no longer accept data. When the transmitting device sees the XOFF it stops sending until it receives an XON from the other end. Each method has its advantages and disadvantages. For example, XON/XOFF needs no extra wires, but response is not instantaneous. Both ends must have some data buffer space and logic to support the handshake.

## 9.2 Standard Data Interfaces

This section covers a set of common data interfaces used in the amateur station. See the **Component Data and References** chapter for details on computer connector pinouts.

### SIGNALING LEVELS

Inside equipment and for short runs of wire between equipment, the normal practice is to use neutral keying; that is, simply to key a voltage such as +5 V on and off. In neutral keying, the off condition is considered to be 0 V. Over longer runs of wire, the line is viewed as a transmission line, with distributed inductance and capacitance. It takes longer to make the transition from 0 to 1 or vice versa because of the additional inductance and capacitance. This decreases the maximum speed at which data can be transferred on the wire and also may cause the 1s and 0s to be different lengths, called bias distortion. Also, longer lines are more likely to pick up noise, which can make it difficult for the receiver to decide exactly when the transition takes place. Because of these problems, bipolar keying is used on longer lines. Bipolar keying uses one polarity (for example +) for a logical 1 and the other (– in this example) for a 0. This means that the decision threshold at the receiver is 0 V. Any positive voltage is taken as a 1 and any negative voltage as a 0.

### EIA-RS-232

The serial bus protocol EIA-RS-232 addresses this issue (however, a Mark "1" is a negative voltage and a Space "0" is positive). Generally called RS-232, this protocol defines connectors and voltages between data terminal equipment (DTE) such as a PC, and data communications equipment (DCE), such as a modem or TNC.

The connector is the DB-25 (25 pin), or DB-9 (9 pin) version — though RS-232 interfaces have also been implemented using nonstandard connectors such as RJ45, 3.5 mm audio plugs and many others. Signaling voltages are defined between +3 V and +25 V for logic "0" and between –3 V and –25 V for logic "1." Although the top data rate addressed in the specification is only 20 kbit/s, speeds of up to 115 kbit/s are commonly used. Communications distances of hundreds of meters are possible at reasonable data rates.

Since neutral keying is usually used inside equipment and bipolar keying for lines leaving equipment, signals must be converted between bipolar and neutral. Discrete level shifters or op amp circuits may perform this task, or low cost specialized IC line drivers and receivers are available.

### UNIVERSAL SERIAL BUS (USB)

USB is a computer standard for an intelligent serial data transfer protocol, and it has become the standard for nearly all connections between a PC and its external peripherals. It has largely replaced serial, parallel, keyboard and mouse ports as well as SCSI and numerous other buses in consumer PCs.

In addition to higher speed than RS-232 and parallel ports, USB offers reasonable power availability to its loads, or functions. Under certain circumstances, up to 127 hubs and functions may connect to a single computer. USB requires that each function have on-board intelligence and that it negotiate with the host for power and bandwidth allocation. USB also has the major advantage of hot-pluggablity — the PC need not reboot when new functions are added.

The USB connectors use four-conductor cable, with two bidirectional, differential data lines, power, and ground. Approximately 5 V at 100 mA is allowed per function, with up to 500 mA available if the host system has the capability. This means that relatively sophisticated devices, such as modems, small video cameras, or hand-held scanners may operate from the bus without additional power supplies. It has also become common to use USB for connecting and charging a wide range of devices such as cellular phones, cameras and GPS units. When a USB connecting cable is used, proper connections and proper flow are ensured by using a rectangular (USB "A") connector on the host and a different connector (USB "B", Mini-B or Micro-B) on the attached function.

There are currently two USB standards in general use. USB 1.1, somewhat obsolete but common in PCs just a few years old, is capable of 12 megabits per second (12 Mbit/s). USB 2.0 is the later standard and is rated up to 480 Mbit/s. Most USB 2.0 ports will allow the use of older USB 1.1 devices — that is, they are backward compatible. However maximum cable lengths and available power to devices may be affected. USB 3.0 uses additional wires and some new connectors to enable communication at up to 5 Gbit/s in its SuperSpeed configuration.

Older PCs that have just one or two USB ports can have additional ports by adding an inexpensive USB port expander, commonly called a USB hub. Some units obtain their power from the host computer's USB port, and distribute only the USB signals along with the remaining power available from the host. Others come with a small power supply that provides the normal power to each new USB port.

If the PC does not have any USB ports, an expansion card can be used to add USB ports. It is quite common to see new personal computers without any serial or parallel ports, with USB replacing these functions. If you need to use your older serial or parallel peripheral devices with these "legacy-free" PC systems, adapter cables are available to connect them to USB ports.

### ETHERNET

For wired networks, 100BaseT or "fast Ethernet" has been the standard for a number of years, with low cost hubs and switches commonly available. The 100BaseT systems are rated to 100 Mbit/s and use unshielded, twisted-pair Category 5 network cable. Each computer on the network connects to a central hub or switch.

More recently, 1000BaseT (gigabit Ethernet, or GigE) and is quickly replacing 100BaseT even at the consumer level. Gigabit Ethernet also uses Cat 5 cable, though Cat 5e or Cat 6 is often recommended. Explanation of the MBaseN and Category N terminology can be found in many available networking books.

Mutual interference with ham station operation is not uncommon. A 10 Mbit/s signal, if all bit positions are filled, means that unshielded wire is carrying 10 MHz and various harmonics of 10 MHz around the shack. When digital words are going through the network, any number of frequencies may be present on the wires and the wires may be very susceptible to pick-up from HF, VHF and UHF signals. In addition, cable and DSL modems may not only transmit various

frequencies (especially on VHF) but lose data when a few hundred watts on a ham band is present. Some RF in the shack that can normally be ignored can easily bring down a network. Unfortunately, it is also common for this equipment to have "noisy" switching power supplies that can wreak havoc on a ham's sensitive receiver. See the **RF Interference** chapter for more information on dealing with RFI from networking equipment.

### WIRELESS NETWORKS — WIFI

The other technology commonly found in home and office networks is IEEE 802.11 wireless. These networks use low-power, spread spectrum transceivers operating in the 2.4 and 5.2-5.8 GHz range to transfer data at nominal rates up to 54 Mbit/s and higher. Older equipment used the 801.11b protocol at 11 Mbit/s; newer gear commonly found at low prices uses 802.11g at 54 Mbit/s maximum data rate. The 802.11n protocol supports data rates up to several hundred megabits per second in the 2.4 and 5 GHz ranges.

These data rates are the maximum under ideal conditions, and it is not uncommon to see links running at significantly lower speeds as the *wireless access point* (WAP) and the wireless adapter dynamically adapt to the conditions. Still, performance is adequate for most uses, and the lack of network cabling makes wireless networking attractive in many situations.

Wireless networks actually appear to be less susceptible to mutual interference, since they are not connected to long runs of unshielded wire that easily act as both transmitting and receiving antennas. The frequency bands used for wireless networks are reasonably far removed from normal ham operations at frequencies below 2.4 GHz, but a high power VHF or UHF station may interfere with such a network. Also, some of the channels used for 802.11b and 802.11g network equipment fall within the amateur spectrum allocation in the 2.4 GHz band.

### CABLE REPLACEMENT — BLUETOOTH AND ZIGBEE

A number of low power, short range data links have been created to replace cable based interfaces such as USB and RS-232. These are digital protocols that use unlicensed spectrum in the ISM bands. Two of the most popular as of early 2013 are Bluetooth (**www.bluetooth.com**) and Zigbee (**www.zigbee.org**). Most technologies of this type are either initially or permanently developed as implementations of an IEEE 802.x standard.

Bluetooth data links operate in the 2.4 GHz band and are primarily used for streaming audio and high speed digital links up to several megabits per second. Bluetooth links use frequency-hopping spread-spectrum technology. It can also support personal area networks (piconets or PANs) at various levels of security. Up to seven devices can share a Bluetooth interface with a host. A process called synchronization is used to associate the various devices.

Zigbee is designed for ad-hoc mesh networking applications and operates in the 902 MHz ISM band in North America. Zigbee's maximum data rate is 250 kbit/sec. Because of the lower data rate, most Zigbee applications are designed for control and monitoring applications.

### REPLACING COM AND LPT PC INTERFACES

USB-to-serial and USB-to-parallel adapters are relatively inexpensive and easy to find. Note, however, that not all of them support all of the handshaking signals we may require, and some may have delays or inadequate drivers. Be prepared to try several different brands to find one that works with your equipment. Users groups for specific equipment or software are good resources to find out what brands and models of port replacement accessories are compatible and operate properly. While they are becoming less common, there is also still a market for add-in PCI bus cards to add serial, parallel and other ports to desktop computers.

# 10 Glossary of Digital Electronics Terms

***AND gate*** — A logic circuit whose output is 1 only when all of its inputs are 1.

***Astable (free-running) multivibrator*** — A circuit that alternates between two unstable states. This circuit could be considered as an oscillator that produces square waves.

***Asynchronous flip-flop*** — A circuit, also called a *latch*, that changes output state depending on the data inputs, without requiring a clock signal.

***Binary*** — A base-2 number system used in digital electronics that uses the symbols 0 and 1.

***Binary coded decimal (BCD)*** — A simple method for converting binary values to and from decimal for inputs and outputs for user-oriented digital systems. BCD was widely used in the days of 7-segment LED displays but is not common today.

***Bistable multivibrator*** — Another name for a flip-flop circuit that has two stable output states.

***Boolean algebra*** — The mathematical system used to describe and design binary used digital circuits, named after George Boole.

***Bus*** —A set of wires through which data is routed internally within computers and other digital devices.

***Clock*** — A signal that toggles at a regular rate. Clock control is the most common method of synchronizing logic circuits.

***Combinational logic*** — A type of circuit element in which the output depends on the present inputs. (Also see **Sequential logic**.)

***Complementary metal-oxide semiconductor (CMOS)*** — A type of construction used to make digital integrated circuits. CMOS is composed of both N-channel and P-channel MOS devices on the same chip.

***Counter (divider, divide-by-n counter)*** — A circuit that is able to change from one state to the next each time it receives an input signal. A counter produces an output signal every time a predetermined number of input signals have been received.

***Decimal*** — The base-10 number system we use every day that uses the symbols 0 through 9.

***DeMorgan's Theorem*** — In Boolean algebra, a way to simplify the complement of a large expression or to enable a designer to interchange a number of equivalent gates.

***Digital IC*** — An integrated circuit whose output is either on (1) or off (0).

***Dynamic (edge-triggered) input*** — A control signal that allows a circuit to change state only when the control signal changes from unasserted to asserted.

***Exclusive OR gate*** — A logic circuit whose output is 1 when either of two inputs is 1 and whose output is 0 when neither input is 1 or when both inputs are 1.

***Fan-out*** — The ability of a logic element

to drive or feed several other logic elements.

***Field Programmable Gate Array (FPGA)*** — A type of programmable logic array that can contain several hundred to millions of logic gates and up to 1000 or more I/O pins.

***FireWire (IEEE-1394)*** — A very high speed serial protocol capable of up to 400 Mbit/s of sustained transfer.

***Flip-flop (bistable multivibrator)*** — A circuit that has two stable output states, and which can change from one state to the other when the proper input signals are detected.

***Gate*** — A combinational logic element with two or more inputs and one output. The output state depends upon the state of the inputs.

***Handshaking*** — Functions to coordinate data transfer.

***Hexadecimal*** — A base-16 number system widely used in computer systems that uses the 0,1,2,3,4,5,6,7,8,9,A,B,C,D,E,F.

***Integrated circuit*** — A device composed of many bipolar or field-effect transistors manufactured on the same chip, or wafer, of silicon.

***Inverter*** — A logic circuit with one input and one output. The output is 1 when the input is 0, and the output is 0 when the input is 1.

***Latch*** — Another name for a bistable multivibrator (flip-flop) circuit. The term latch reminds us that this circuit serves as a memory unit, storing a bit of information.

***Linear IC*** — An integrated circuit whose output voltage is a linear (straight line) representation of its input voltage.

***Logic probe*** — A simple piece of test equipment used to indicate high or low logic states (voltage levels) in digital-electronic circuits.

***Microcontroller*** — A "computer on a chip" that usually consists of a relatively small microprocessor along with some amount of program memory, data memory, input/output ports and often some specialized peripheral devices.

***Monostable multivibrator (one shot)*** — A circuit that has one stable state. It can be forced into an unstable state for a time determined by external components, but it will revert to the stable state after that time.

***NAND (NOT AND) gate*** — A logic circuit whose output is 0 only when both inputs are 1.

***Noninverter*** — A logic circuit with one input and one output, and whose output state is the same as the input state (0 or 1). Sometimes called a *noninverting buffer*.

***NOR (NOT OR) gate*** — A logic circuit whose output is 0 if either input is 1.

***OR gate*** — A logic circuit whose output is 1 when either input is 1.

***Parallel*** — A digital signaling method in which all the bits in a group are handled exactly at the same time.

***Programmable logic device (PLD)*** — A device that includes a generic array of gates that can be controlled by program code. PLDs can be made to replace large numbers of individual ICs.

***Propagation delay*** — The time delay between providing an input to a digital circuit and seeing a response at the output.

***Register*** — A set of latches or flip-flops storing an n-bit number.

***RS-232*** — The most common serial bus protocol.

***RS-422*** — A serial protocol similar to RS-232, but employing fully differential data lines.

***Serial*** — A digital signaling method in which each bit is sent in turn over a single channel or wire, according to an agreed sequence.

***Sequential logic*** — A type of circuit element in which the output depends on the present inputs, the previous sequence of inputs and often a clock signal. (Also see **Combinational logic**.)

***Square wave*** — A periodic waveform that alternates between two values, and spends an equal time at each level. It is made up of sine waves at a fundamental frequency and all odd harmonics.

***Static (level-triggered, or gated) input*** — A control signal that allows the circuit to change state whenever the control signal is at its active or asserted level.

***Synchronous flip-flop*** — A circuit whose output state depends on the data inputs, but that will change output state only when it detects the proper clock signal.

***Transition region*** — The undefined region between the two binary states. Also known as the *noise margin*.

***Transition time*** — The time it takes a digital circuit to change state. The transition from a 0 to a 1 state is called the *rise time*, and the transition from a 1 to a 0 state is called the *fall time.*

***Tri-state gate*** — A gate with one additional control lead. When enabled, the gate operates normally; when not enabled, the output goes to a high impedance.

***Truth table*** — A chart showing the outputs for all possible input combinations to a digital circuit.

***Universal serial bus (USB)*** — A computer standard for an intelligent serial data transfer protocol.

# Image Communications

This supplement covers two popular communication modes that allow amateurs to exchange still or moving images over the air. Advances in technology have made image communications easier and more affordable, resulting in a surge of interest.

The first part of this chapter, updated for this chapter by Tom O'Hara, W6ORG, describes fast-scan television (FSTV), also called simply amateur television (ATV). ATV is full-motion video over the air, similar to what you see on your broadcast TV. Because of the wide bandwidth required for ATV signals, operation takes place on the UHF and microwave bands.

The second part of this chapter, updated by Larry Peterson, WA9TT, describes slow-scan television (SSTV). Instead of full motion video, SSTV requires from 8 seconds for a black-and-white image to 1-2 minutes for a full-color image. SSTV is a narrow bandwidth image mode designed to use voice transceivers — SSB on the HF bands and FM on VHF and higher frequencies. SSTV is also supported by repeaters, satellites, and the ISS.

Unless otherwise noted, references to other chapters refer to chapters in the print version of the *ARRL Handbook*.

## 1 Fast-Scan Amateur Television Overview

Fast-scan amateur television (FSTV or just ATV) is a wideband mode that is based on the analog *NTSC* (National Television System Committee) standards used for broadcast television in the US for many years, before most broadcasters switched to digital transmission in 2009. Analog AM and FM ATV use standard NTSC television scan rates. It is called "fast scan" only to differentiate it from slow-scan TV (SSTV) or digital TV (DTV). In fact, no scan conversions or encoders/decoders are necessary with analog ATV.

Any standard TV set capable of displaying analog NTSC broadcast or cable TV signals can display the AM Amateur Radio video and audio signals. Since 2008, new consumer digital television (DTV) sets sold in the US are designed to receive high definition television (HDTV) broadcasts using the 8-VSB (8-level Vestigial Side Band) standard from the Advanced Television Systems Committee (ATSC). DTV televisions also include analog AM and Digital Cable (D-CATV) channel tuners and cable quadrature amplitude modulation (QAM) tuners per FCC Rule 15.118(c). It is a good idea however, to not dispose of your old analog-only televisions, but keep them for ATV. Analog AM ATV on the 70 cm band will be the primary ATV system for some time given its low cost, size, and ease to get on.

To transmit ATV signals, standard RS-170 composite video (1-V peak-to-peak into 75 Ω) or 480i/30 NTSC and line audio from home camcorders, cameras, DVD/VCRs, DVRs, or computers is fed directly into a transmitter designed for the ATV mode. The audio goes through a 4.5 MHz FM subcarrier generator in the ATV transmitter that is mixed with the video. It is the same for FM ATV, but the sound subcarrier can be anything from 4.5 MHz to 6.8 MHz, with 5.5 MHz typical.

Picture quality is about equivalent to that of a VCR, depending on video signal level and any interfering carriers. All of the sync and signal-composition information is present in the composite-video output of modern cameras and camcorders. Most camcorders have an accessory cable with RCA phono plugs that provide separate audio/video (A/V) outputs. Security video cameras with A/V plugs or noted as CVBS (composite video baseband signal) are also popular. Analog HD, HDcctv, HD-TVI, AHD, HD-SDI, IP or other cameras use different video standards and cannot be used for analog NTSC ATV unless they first go through a conversion in a DVR or other device. Audio output may vary from one camera to the next, but usually it has been amplified from the built-in microphone to between 0.1 and 1 V P-P (into a 10-kΩ load).

### 1.1 ATV Activities

Amateurs regularly show themselves in the shack, zoom in on projects, show home video recordings, televise ham club meetings and share just about anything that can be shown live or recorded (see **Figures 1** and **2**, application notes at **www.hamtv.com/info.html,** and **www.kh6htv.com/application-notes**). Whatever the camera "sees" and "hears" is faithfully transmitted, including full motion color and sound information. Computer graphics and video special effects are often transmitted to dazzle viewers. Several popular ATV applications are described in detail later in this chapter.

**Figure 1 — Students enjoy using ATV to communicate school to school or between classrooms (top). The ATV view shows the aft end of the Space Shuttle cargo bay during a mission (bottom).**

**Figure 2 — The one-way ATV DX record is held by KC6CCC in San Clemente, California, for reception of 434-MHz video from KH6HME in Hawaii during a tropo opening in 1994. The distance is 2518 miles. See www.hamtv.com/atvdxrecord.html.**

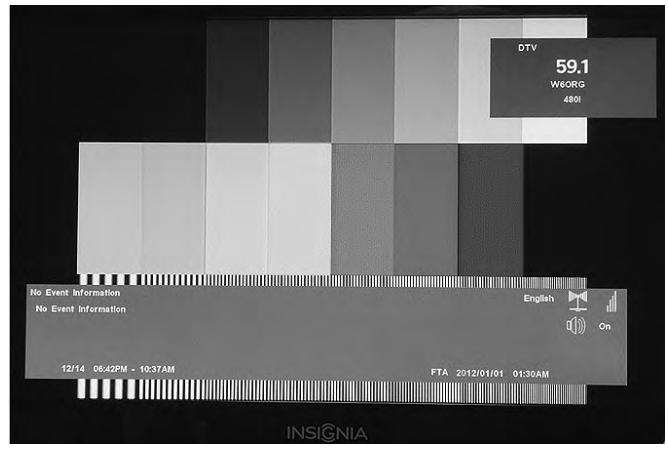

**Figure 3 — When the info or display button is pushed on newer digital TV's remote control, the D-CATV channel number may be a Virtual Channel designation from 1 to 999 (and not the actual transmitted channel programmed in the DTV modulator), along with the station call and other information. Channel 59.1 is shown, but the actual transmitter channel was 58 and does not change if the frequency is changed. Analog channels are shown without the decimal point or with a decimal point or dash and a zero. Digital channels are shown with a major number, decimal point or a dash and a minor number. The minor numbers indicate that this channel may have more than one video or program.**

## 1.2 Comparing Analog AM, FM and Digital ATV

Receiving ATV using any of the three ATV modes is relatively easy using consumer televisions and receivers directly, or with the addition of an amateur band receive converter (downconverter). Much of the activity in an area depends on the first few hams who experiment with ATV, and on the cost and availability of equipment for others to see their first picture.

Most older analog-only TVs that do not have active channel memory scan setup and don't have video squelch that goes to blank or blue screen when no signal is present are preferred by ATV DXers as they can continuously search or monitor for ATV signals in the snow easily. Newer TV's have an active channel scan setup that searches for analog and digital channels and skips those that are found not to be active. If you have cable, most likely it will have active cable channels 57-60 (direct 70 cm ATV), 3 and 8 (downconverter output) and be available for use on ATV if you have done the setup scan while connected to your cable service. If you do not have a cable service, your TV may or may not let you manually add a channel if no signal is present. You may have to get a local ATVer to send you a signal that is strong enough as you do the channel scan. This will also be the case with over the air digital 8-VSB and cable QAM transmissions. DVB-T and DVB-S will require a receiver or set top box connected to your newer TV's HDMI monitor input, and also require an active channel scan.

The frequency reference for an analog AM transmission is the video carrier which is 1.25 MHz up from the lower channel edge. A digital transmission is referenced as the center frequency — for instance, cable channel 57 AM is 421.25 MHz, digital is 423.0 MHz in the same 420-426 MHz range. Note that D-CATV stations can present as Virtual Channels or Logical Channel Numbers which may not be the actual transmitted channel when detected by the TV setup channel scan. If your TV info overlay says you have a valid digital channel 59.1, it could actually be transmitted on a different channel. The station ID, channel and info are transmitted with the video and any text can be programmed into the modulator as seen in **Figure 3** for whatever purpose the cable operator has.

Analog AM TV on the 70 cm band is the easiest mode to get on and can be found with the weakest signal. The 70 cm ham band contains the same frequencies as analog cable channels 57 through 61 which makes it practically no cost, other than a 70 cm antenna, to see your first AM ATV picture. Simple 70 cm ATV transmitters are available that are low cost, small, and draw less current than the other ATV modes. This is desirable for R/C (radio control), high altitude balloon, rocket and portable emergency communications or public service events. Call letter IDs with 70 cm AM ATV can be seen at much greater range, although with a lot of snow in the picture, and is the favorite of DXers. Adding a linear amplifier requires an initial drive setup so as to keep the video modulation within the linear range.

FM ATV also uses simple transmitters, but most activity is on the 13 cm, 23 cm and 33 cm amateur bands. This is in part because of the wide occupied bandwidth needed for FM ATV signals, and in part because of the availability of receivers originally designed for commercial C-band satellite or unlicensed Part 15 use. The FM receivers have analog

**Figure 4 — The Hi-Des HV-100EH DVB-T modulator is shown here driving a KH6HTV 70-7B linear amplifier on the 70 cm band. The modulator also tunes the 33 cm band and has an adjustable output up to –3 dBm for driving a high linearity MMIC and FET power amplifier. Transverters can be used for operation on the higher frequency bands.**

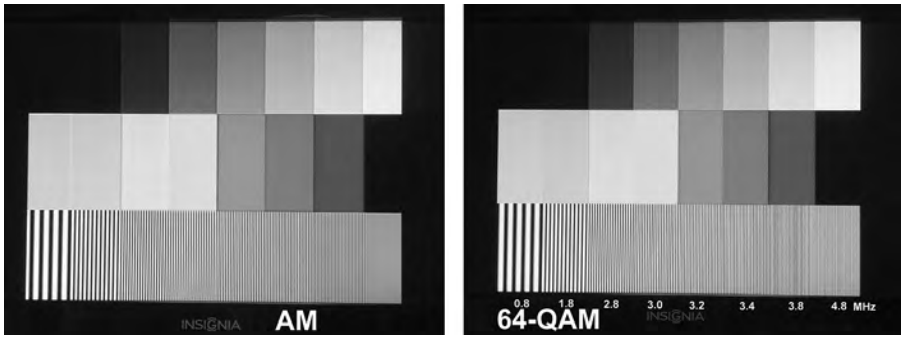

**Figure 5 — These two images compare P5 test patterns from an AM analog transmitter and a D-CATV 64-QAM transmitter. The 4.8 MHz multiburst vertical lines can be seen in the 64-QAM 480i picture ,but the AM is rolled off to grey and is limited to resolving the 3.8 MHz burst lines**

A/V outputs that must be connected to a video monitor and not a channel 3 analog RF modulator to a TV in order to see the best picture resolution possible. Less care need be given to driving power amplifiers than when using AM or digital modulation.

Digital Video Broadcast–Terrestrial (DVB-T) set for 2, 4 or 6 MHz QPSK has become the preferred digital ATV mode because it takes the least signal level to lock in the picture. Equipment for this DTV mode has become available at lower cost than the others. Set top box receivers can be found on the internet at low prices, but most need a good preamp, will not receive 2 or 4 MHz modulation and some tuners cannot be made to lock on to the 70 cm ham frequencies without a downconverter. Modulators are available for DVB-T the ham bands (**Figure 4)**. RF amplifiers for DTV however, are more critical as to drive level, linearity and low inter-modulation distortion than with analog AM or FM ATV modes. DVB-T does well with motion and multipath among the DTV types. High definition 1080p video can be run in a 6 MHz channel and 480i in a 2 MHz channel. However, 1080p can also be run in a 2 MHz channel but pixilation, freezing, smearing and longer latency can occur depending on motion and how many pixels are changing. DTV can have higher resolution (**Figure 5**) than AM because they do not have a sound subcarrier that limits the video bandwidth.

Cable Quadrature Amplitude Modulation — (QAM) is easy to receive with newer TV's since 2012, but requires the most signal strength of the DTV modes. Cable QAM (D-CATV) uses the North American ITU-T J.83B protocol which is different in the USA compared to Digital Video Broadcast – Cable (DVB-C) in most of the rest of the world. Cable head-end modulators such as the Drake DSE24 are available and prices have been coming down.

ATV running Digital Video Broadcast–Satellite (DVB-S) often uses "free to air" receivers made for satellite TV reception in Europe and other parts of the world and can be found on the internet at reasonable prices. Board level modulators are also available. DVB-S is better as far as weak signal reception, multipath and motion than D-CATV but not DVB-T. DVB-S is more forgiving as far as amplifier linearity and IMD.

Gear made for WiFi can be used for ATV if the transceivers are set for the Part 15 channels shared with the ham bands, or modified with firmware to move completely into the ham band. See the discussion of Broadband-Hamnet in the **Digital Protocols and Modes** chapter and **www.AREDN.org** which is primarily aimed at emergency communications. IP cameras can be plugged into Nano Stations, transmitted to a Hamnet node or receiver, and viewed on a computer screens.

Digital ATV signals using the USA broadcast DTV standard Eight–Vestigial Sideband (8-VSB) can also be received simply by using televisions made after 2008 in the same manner as analog cable televisions. Although modulator prices are coming down, the transmitters are expensive due in part to complexity and also to patent restrictions. 8-VSB is fine for fixed station to fixed station, but does not work for mobile even at slow speeds. A good comparison and description of 8-VSB and COFDM (Coded Orthogonal frequency-division multiplexing) which is used by DVB-T, and C-DATV can be found at **en.wikipedia.org/wiki/8VSB**.

## PICTURE QUALITY

Experimentally, using the US standard, FM ATV gives increasingly better picture-to-noise (snow) ratios than AM analog ATV at receiver input signals greater than 5 μV. That's also about the signal level for the 8-VSB DTV "cliff effect" where the signal disappears. The DTV all-or-nothing cliff effect occurs because the digital signal detector and processing in the receiver require a signal-to-noise ratio (SNR) of at least 15 dB for 8-VSB. Above 15 dB, you get an excellent picture, and at 14 dB SNR — nothing. Other DTV types — DVB-S or DVB-T — are a few dB better in the presence of noise depending on the bandwidth, mode and other factors.

Because of the wider noise bandwidth and FM threshold effect, AM analog video can be seen in the noise well before FM and DTV. For DX operation, it has been shown that AM

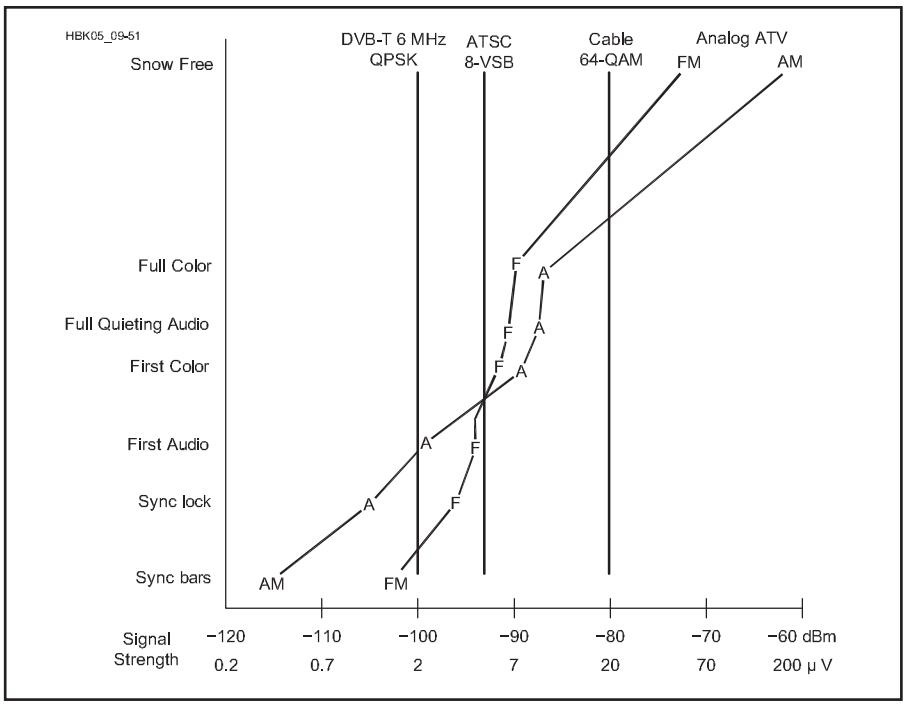

**Figure 6 — Three approaches to ATV receiving. This chart compares AM, FM anddigital ATV as seen on a TV receiver and monitor. Except for DVB-T, signal levels are into the same downconverter with sufficient gain to be at the noise floor. The FM receiver bandwidth is 17 MHz, using the US standard. The three straight vertical lines for DTV illustrate the cliff effect described in the text.**

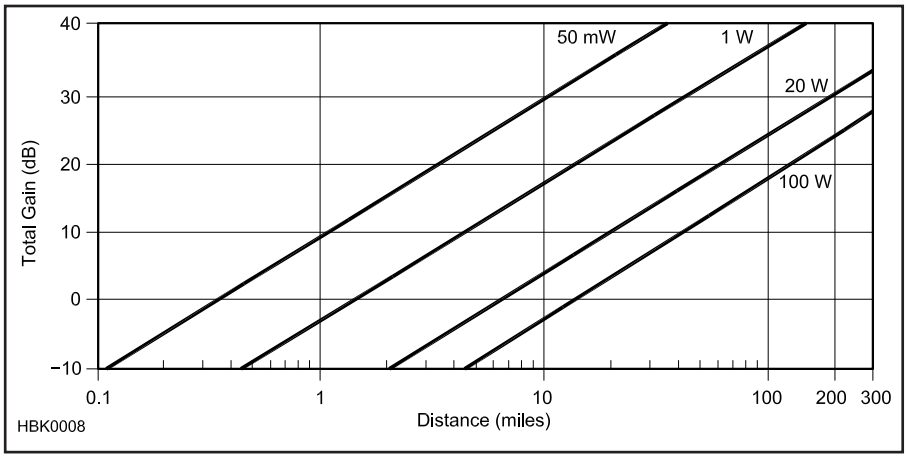

**Figure 7 — This graph shows the possible line-of-sight distances for P5 (snow free) video reception for various analog AM ATV transmitter levels in the 70 cm band. Power levels shown are in PEP. The Total Gain is calculated by adding the antenna gain (dBd) for both the receive and transmit antennas and then subtracting the feed line loss (in dB) at both ends. For other bands: 33 cm, subtract 6 dB; 23 cm, subtract 9 dB; and 13 cm, subtract 15 dB. For FM ATV (4 MHz deviation, 5.5 MHz sound), add 12 dB. For DVB-T digital TV, the sudden loss of picture "cliff effect" distance is found by adding 39 dB. If the noise figure of the first stage in the downconverter is greater than 2 dB, subtract for each dB over 2. See the example in Table 1.**

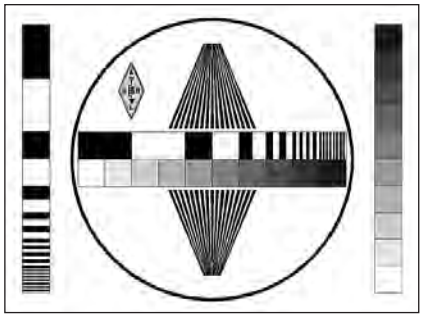
signals are recognizable in the snow at up to four times (12 dB) greater distance than FM, with all other factors equal. Above the FM threshold, however, FM rapidly overtakes AM. FM snow-free pictures occur above 50 µV, or four times farther away than with AM signals. The crossover point is near the signal level where sound and color begin to appear for both systems. **Figure 6** compares analog AM, FM and digital ATV across a wide range of signal strengths.

DTV does not have the video resolution limitation of a 3.58 MHz color subcarrier as does NTSC AM and FM ATV. For DX or local ragchewing, resolution or snow free picture may not be a significant factor, but when using ATV for public service events, a crisp solid screen is a welcome benefit for coordinators. Video resolutions greater than NTSC 480i are possible with DTV running digital cameras and a modulation bandwidth of 6 MHz. 720p and 1080p are the most popular and picture aspect ratios are 4:3 or 16:9.

**Table 1**
**ATV DX Graph Example**

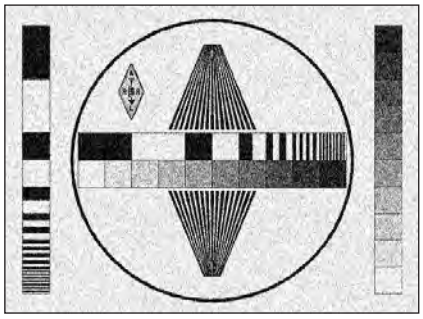
| | |
|---|---|
| Transmit antenna | +10 dBd |
| Receive antenna | +12 dBd |
| Transmit feed line | –1 dB |
| Receive feed line | –2 dB |
| 6 dB noise figure | –4 dB |

Total Gain for 70 cm is 15 dB
With 20 W PEP, range is 35 miles (Figure 7)



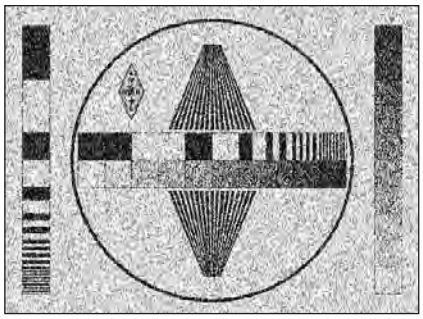
For 23 cm (–9 dB) gain is 6 dB
With 1 W PEP, range is 3 miles (Figure 7)

## 1.3 How Far Does ATV Go?

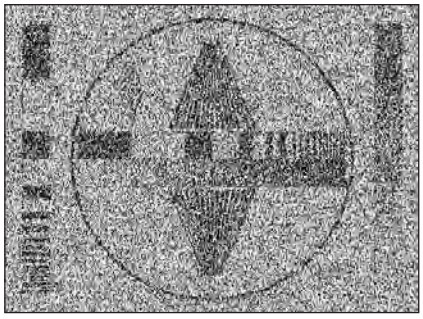


The theoretical snow-free line-of-sight distance for 20-W PEP 70 cm analog AM ATV, given 15.8-dBd gain antennas and 2 dB of feed line loss at both ends, is 150 miles. (See **Figure 7**.) In practice, direct line-of-sight ATV contacts seldom exceed 25 miles due to the curvature of the Earth with hills and buildings blocking the direct path. Longer distances are possible with over-the-RF-horizon tropo openings, reflections, or through high hilltop repeaters. A 2518-mile reception record is shown in Figure 2. (See the **Propagation of Radio Signals** chapter.) West Coast hams use the Hepburn Tropo Ducting Forecast at **www.dxinfocentre.com/tropo_wam.html** for openings, especially in the summer months to know when best to listen for the Hawaii beacons. The best initial indication that you have a path to a local ATVer or ATV repeater is how strongly you receive their 2 meter FM voice signal. There are internet web sites that can give you RF coverage maps such as Radio Mobile - **www.ve2dbe.com/rmonline.html** and CRC-COVWEB at **lrccov.ca/main**. Some ATV repeater web sites have a coverage map you can check to see what the expected signal strength is for your QTH — see **www.atn-tv.org/maps.htm**.

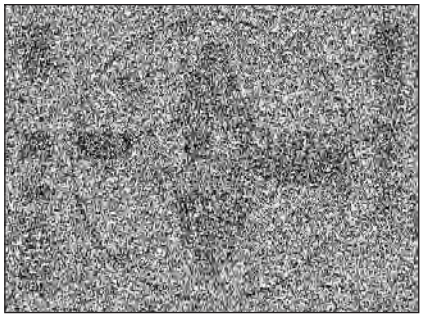
The antenna system is the most important part of an ATV system because it affects both receive and transmit signal strength. For best DX, use low-loss feed line and a broadband high-gain antenna, up as high as possible.



A snow-free, or "P5," picture rating (see **Figure 8**) requires at least 200 µV (–61 dBm) of signal at the input of the analog AM ATV



**P5 — Excellent**



**P4 — Good**

**P3 — Fair**

**P2 — Poor**

**P1 — Barely perceptible**

**Figure 8 — An ATV quality reporting system.**

receiver, depending on the system noise figure and bandwidth. The noise floor increases with bandwidth. Once the receiver system gain and noise figure reaches this floor, no additional gain will increase sensitivity. At 3-MHz bandwidth the noise floor is 0.8 μV (–109 dBm) at standard temperature in a perfect receiver. Analog TV luminance bandwidth rolls off around 3 MHz to separate it from the color subcarrier at 3.58 MHz. If you compare this 3 MHz bandwidth to an FM voice receiver with 15 kHz bandwidth, there is a 23 dB difference in the noise floor.

Much like the ear of an experienced SSB or CW operator, however, the eye can pick out sync bars in the noise below the noise floor. Sync lock and large, well contrasted objects or lettering can be seen between 1 and 2 μV with AM ATV. Color and subcarrier sound come out of the noise between 2 and 8 μV depending on their injection level at the transmitter and characteristics of your TV set. For the ATV DXer, using an older analog TV that does not go to blue screen or go blank (like a video squelch) with weak signals is a must, especially when rotating the antenna for best signal.

With DTV you get a perfect picture if the signal strength is above the cliff, and nothing or freeze-frame, if below. In multipath conditions the DVB-T transmitting station can try increasing the FEC and reducing the guard interval fractions as well as reducing the data rate to get a good enough picture with only a non-moving call sign in the picture. It can be more difficult and time consuming to swing the beam looking for a DTV signal because it can take as much as 10 seconds depending on the DTV mode set up for the receiver to lock on and decode the video. It is best to rotate the antenna in small increments, generally the 3 dB beam width of the beam, wait, and keep trying until found. Then split the difference of the beam headings from where the picture freezes or disappears.

Operators must take turns transmitting on the few available channels. Two meter FM is used to coordinate ATV contacts and the 2 meter link allows full-duplex audio communication between many receiving stations and the ATV transmitting station speaking on the sound subcarrier. This is great for interactive show and tell. It is also much easier to monitor a squelched 2 meter channel using an omnidirectional antenna rather than searching out each station by rotating a beam. Depending on the third-harmonic relationship to the video on 70 cm, 144.34 MHz and 146.43 MHz (simplex) are the most popular frequencies. The 2 meter audio is often mixed with the subcarrier sound on ATV repeater outputs so all can hear the talkback. If running DTV, you do have to have patience and get used to the delay or latency, which can vary from tenths of a second to 10 seconds depending on the mode, bandwidth and other factors. It takes time for the digital encoders and decoders to lock on and process the video data.

# 2 Amateur TV Systems

Regardless of the type of ATV you're interested in — analog AM, FM or digital — you'll need to assemble the appropriate receiving and transmitting equipment and find other stations to work. A basic AM 70 cm ATV station is shown in **Figure 9**. Very few multimode transmitters and transceivers support the broadband ATV mode and therefore most use equipment specifically designed for ATV. Sending video is easy by plugging in to the ATV transmitter your camcorder, video camera, digital camera, VCR, DVR, or any device with standard video output (usually RS-170 or CVBS) that can be viewed on an analog video monitor, VCR or a TV set's video input.

## 2.1 Analog AM ATV

**Figure 10** shows the makeup of an analog AM TV channel (also called an NTSC channel) used for ATV, cable TV and for broadcast TV before the switch to digital. The channel is 6 MHz wide to accommodate the composite video, 3.58 MHz color subcarrier and 4.5 MHz sound subcarrier. Given the NTSC 525 horizontal line and 30 frames per second scan rates, the resulting horizontal resolution bandwidth is 80 lines per MHz. Therefore, with the typical TV set's 3-dB rolloff at 3 MHz (primarily in the IF filter), up to 240 vertical black lines can be seen. The horizontal scan lines are interlaced and this old NTSC standard is often noted as 480i/30. Newer TVs have better filters resulting in higher resolutions. Color bandwidth in a TV set is less than this, resulting in up to 100 color lines. Lines of resolution are often confused with the number of horizontal scan lines per frame. The video quality should be every bit as good as on a home video recorder. DXers, however, may add a 1 MHz or less band-pass filter between the downconverter and TV input on channel 3 to reduce the noise floor to dig out sync bars or black call letters.

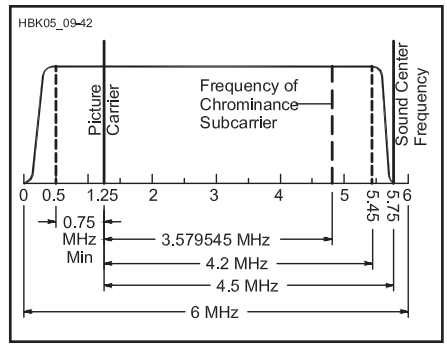


**Figure 10 — An analog VSB NTSC 6 MHz video channel with the video carrier 1.25 MHz up from the lower edge. The color subcarrier is at 3.58 MHz and the sound subcarrier at 4.5 MHz above the video carrier.**

Most ATV is analog AM double sideband (DSB), with the widest component being the sound subcarrier out ±4.5 MHz. As can be seen in **Figure 11**, the video power density is down more than 30 dB at frequencies greater than 1 MHz from the carrier — more than 90% of the spectrum power is in the first 1 MHz on both sides of the carrier.

To fit within a 6 MHz wide channel, NTSC broadcast stations used an approach called vestigial sideband (VSB). VSB involves sup-

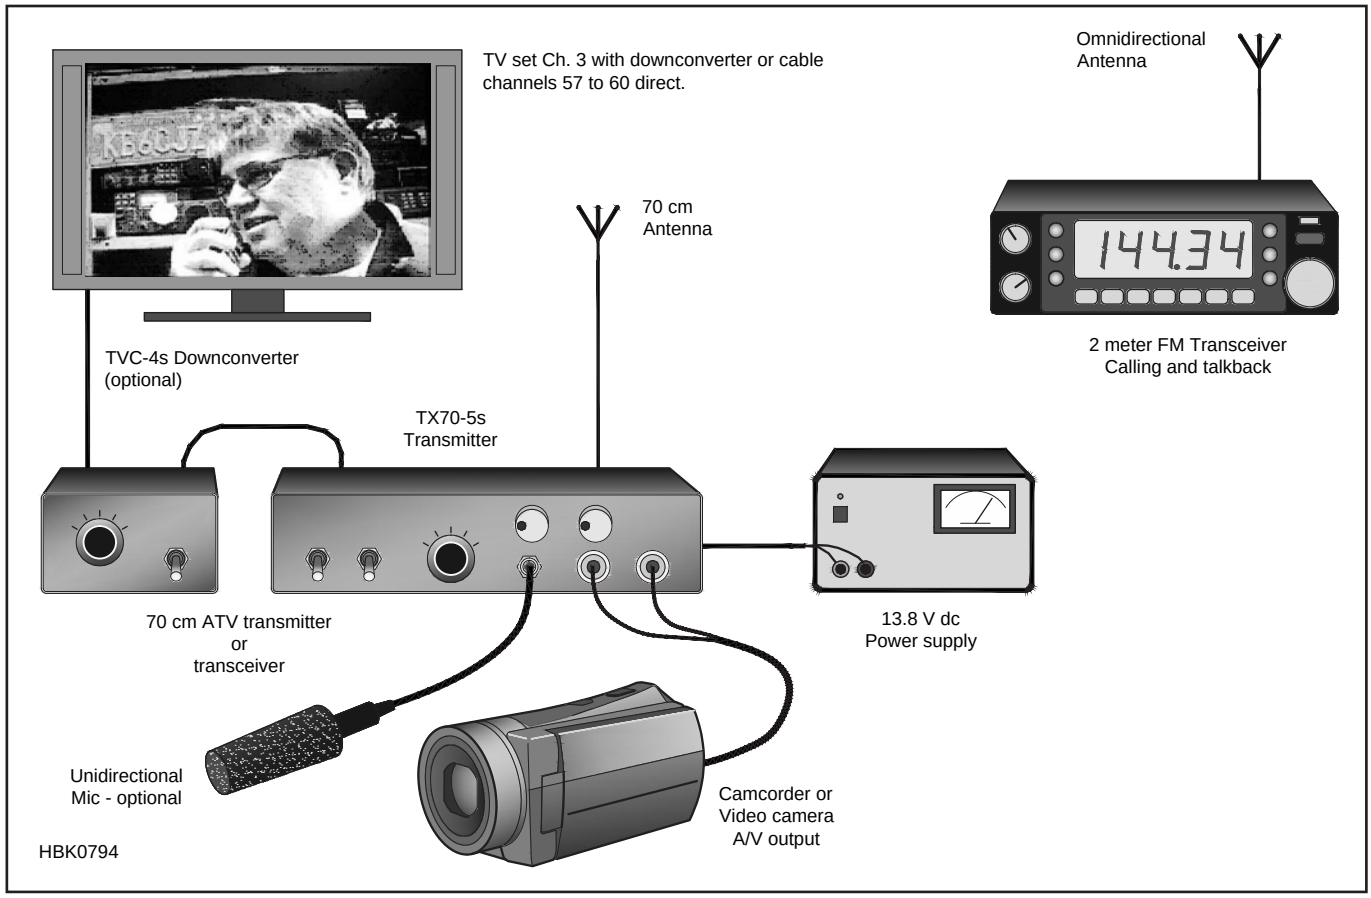

**Figure 9 — Block diagram of a basic 70 cm AM ATV station with an optional downconverter. A TV set can be used without a downconverter, but it's better to have one for weak signal DX and if the video carrier frequency is more than 1 MHz from the cable channel frequency. If receiving an AM or DTV crossband repeater output on 33 or 23 cm, the downconverter would be connected to its own antenna and not through the TR relay in the transmitter. This makes it possible to see your own video coming back.**

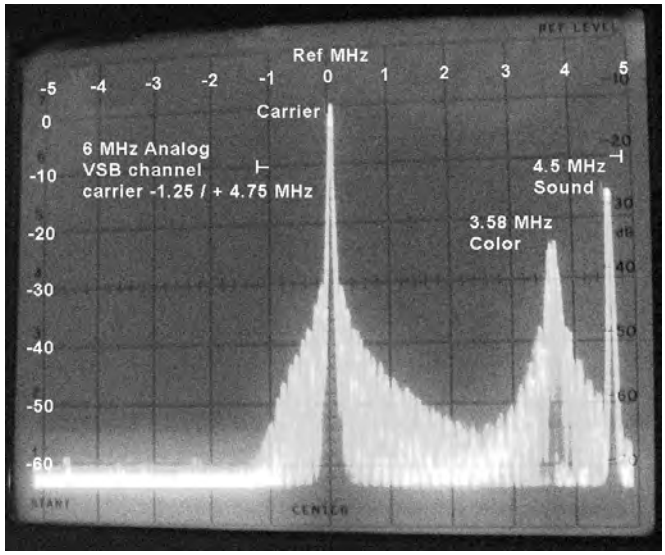

**Figure 11 — Spectral display of a color analog AM VSB ATV signal. Spectrum power density varies with picture content, but typically 90% of the sideband power is within the first 1 MHz.**

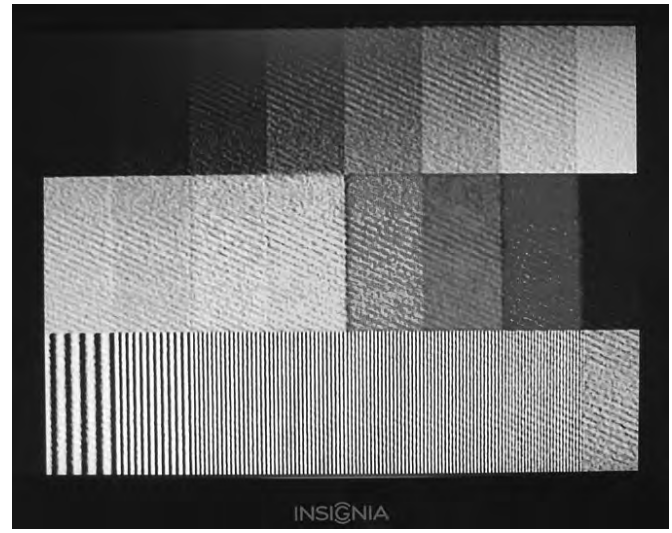

**Figure 12 — AM ATV interference susceptibility. Notice the crosshatch lines from an interfering –100 dBm carrier 1 MHz above the –60 dBm video carrier frequency into the TV receiver.**

pression, but not elimination, of the lower sideband so that it occupies less than 1 MHz. In addition, instead of modulating a 4.5 MHz subcarrier to produce sound, broadcast stations used a second sound transmitter offset above the video carrier by 4.5 MHz so that the sound signal does not appear in the lower sideband.

DSB and VSB are both compatible with analog cable TV tuners, but the lower sound and color subcarriers are rejected in the TV set IF filter as unnecessary. In the case of VSB, less than 5% of the lower sideband energy is attenuated. The other significant energy frequencies are the sound (set in the ATV transmitter at 15 dB below the peak sync) and the color at 3.58 MHz (greater than 22 dB down).

## AM ATV FREQUENCIES

The lowest frequency amateur band wide enough to support an analog AM ATV channel is 70 cm (420-450 MHz), and it is the most popular. With transmit power, antenna gains and feed line losses equal, decreasing frequency increases communication range. The 33 cm (902-928 MHz) band generally covers half the distance that 70 cm does, but this can be made up to some extent with high-gain antennas, which are physically smaller at the higher frequency. Depending on local band plan options, there is room for no more than two simultaneous AM ATV channels in the 33 cm and 70 cm bands without potential interference. Similar to over-the-air broadcast TV, adjacent channels are skipped to avoid interference from a stronger station immediately adjacent to a weaker one. Cable channels don't have that problem because they equalize the amplitude of all the channels. If there is an in-band ATV repeater, simplex ATV operation shares space with the repeater input. Before transmitting, check with local ATV operators, repeater owners and frequency coordinators listed in the *ARRL Repeater Directory* for the coordinated frequencies used in your area.

The most popular in-band repeater output frequency is 421.25 MHz and is the same as cable channel 57. At least 12 MHz of separation is necessary for in-band repeaters because of TV-set adjacent-channel rejection and VSB filter characteristics. Cross-band ATV repeaters free up a channel on 70 cm for simplex and make it easier for repeater users to monitor their own repeated video with only proper antenna separation needed to prevent receiver desensitization.

Simplex, public service and R/C models use 426.25 MHz in areas with cross-band repeaters, or as an alternative to the main ATV activities on 434.0 or 439.25 MHz. The spectrum power density is so low at frequencies greater than 1 MHz from the video carrier of an AM analog ATV transmission that interference potential to other modes is low

On the other hand, interference potential *to* ATV *from* other modes is high. Because a TV set receives a 6-MHz bandwidth, analog AM ATV is more susceptible to interference from many other sources than are narrower bandwidth modes. Interference 40 dB below the desired signal can be seen in video in **Figure 12**. Many of our UHF (and higher) amateur bands are shared with radar and other government radio positioning services. Signals from these services show up as horizontal bars or popping in the picture. Interference from amateurs who are unaware of the presence of the ATV signal (or in the absence of a technically sound and publicized local band plan) can wipe out the sound or color, or can create diagonal lines in the picture.

Other stations operating on narrowband modes more than 1 MHz above or below the video carrier rarely experience interference from an AM ATV signal, or even know that the ATV transmitter is on the air, unless the narrowband station is operating on one of the subcarrier frequencies or the stations are too near one another.

If the band is full and the lower sideband color and sound subcarrier frequencies need to be used by a dedicated link or repeater, a VSB filter in the antenna line can attenuate them another 20 to 30 dB, or the opposite antenna polarization can be used for more efficient packing of the spectrum.

Since the level of intermodulation distortion (IMD) found in most amateur linear amplifiers reinserts the lower sideband to within 10-20 dB of DSB, a VSB filter in the antenna line is a sure and cost-effective way to reduce the unnecessary lower sideband subcarrier energy if more than 1 W is used. VSB cable modulators can also be used if strict attention is made to keep the drive level in the proper range of highly linear amplifiers. In the more populated areas, 2 meter calling or coordination frequencies are often used to work out operating time shifts or other techniques to accommodate all users sharing or overlapping the same segment of the band.

## RECEIVING AM ATV

Since the 70 cm band corresponds to cable

TV channels 57 through 61, seeing your first ATV picture may be as simple as connecting a good outside 70 cm antenna (aligned for the customary local polarization) to a cable-ready TV set's antenna input jack. Your broadcast TV antenna, twin-lead or RG-6 coax may not be good enough for receiving the much lower power ATV transmissions. Cable channel 57 is 421.25 MHz, and each channel is progressively 6 MHz higher. (Note that analog cable channels and the old NTSC broadcast UHF channel frequencies are different above channel 13.) Check the *ARRL Repeater Directory* for a local ATV repeater output that falls on one of these cable channels. Cable-ready TVs may not be as sensitive as a low-noise downconverter designed just for ATV, but this low cost technique is well worth a try. A higher gain antenna and/or low noise antenna preamp, preferably at the antenna, can be added later if the picture has snow in it.

Many newer TVs have to scan which channels and mode are active to retain in tuner memory. If your cable provider is running NTSC and channels 57 through 60 are active, then you are set to go. If not, then hopefully there is a nearby ATVer with a strong enough signal you can receive when you do the channel memory scan or who is willing to come over and transmit into a dummy load as a signal source.

Most stations use a variable tuned or crystal referenced downconverter specifically designed to convert the whole amateur band down to a VHF TV channel. Generally the 420 and 902 MHz bands are converted to TV channel 3 or 4, whichever is not used for over-the-air broadcast TV in the area. For 1240 MHz converters, channels 7 through 10 are used to get more mixer image rejection.

The downconverter consists of a low-noise preamp, mixer and tunable or crystal-referenced local oscillator. Any RF at the input comes out at the lower frequencies. All signal processing of the AM video and FM sound is done in the TV set. A complete receiver with video and audio output would require all of the TV set's circuitry except the sweep and video display components. There is no picture quality gain by going directly from a receiver to a video monitor (as compared with a TV set) because IF and detector bandwidth are still the limiting factors. The Automatic Frequency Control (AFC) in a TV will normally lock on to a video carrier over a little more than ±1 MHz, so frequency drift and accuracy are not nearly as significant as experienced with voice modes. For instance, a TV set to cable channel 59 (433.25 MHz) will normally lock on to a 434.0 MHz ATV signal.

A good low-noise amateur downconverter with 15 dB gain ahead of a TV set will give sensitivity close to the noise floor. A preamp located in the shack will not significantly increase sensitivity, but rather may reduce dynamic range and increase the probability of intermodulation interference. Sensitivity can best be increased by reducing feed line loss or increasing antenna gain. Or you can add an antenna-mounted preamp, which will eliminate the effects of loss in the feed line and loss through TR relays in the transmit linear amplifier. Each 6 dB total improvement — usually a combination of increased transmitter power, antenna gain or receiver sensitivity and reduced feed line loss — can double the line-of-sight distance or improve quality by 1 P unit (a measure of picture quality).

## DRIVING AMPLIFIERS WITH AM ATV

Linear amplifiers for use with wideband AM video require some special design considerations compared to amplifiers used for FM and SSB voice operation. Many high-power amateur amplifiers would oscillate (and possibly self destruct) from high gain at low frequencies if feedback networks and power RF chokes did not protect them. These same stability techniques can affect operation over a 5-MHz video bandwidth. Sync, color and sound can be distorted unless the amplifier has been carefully designed for both stability and AM video modulation.

A few manufacturers offer special ATV amplifiers or standard models designed for all modes, including ATV. The collector and base bias supplies have a range of capacitors to keep the voltage constant under video modulation, while at the same time using the minimum-value low-resistance series inductors or chokes to prevent self-oscillation. Amplifiers using LDMOS devices have better linearity and lower IMD characteristics which are desirable for ATV.

Almost all amateur linear power amplifiers exhibit some degree of gain compression from half-power to their full rated PEP output. For proper AM ATV operation, the amplifier can be driven to PEP output power of no more than its 1 dB gain compression level. If more power is needed, the analog AM ATV exciter/modulator can use a sync stretcher to maintain the proper transmitted video-to-sync ratio to compensate for higher outputs (see **Figure 13**).

To adjust a station with an ATV amplifier, disconnect the video source and set the pedestal control in the ATV transmitter's modulator for maximum power output. Then set the transmitter's RF power control to drive the amplifier to 90% of rated PEP output (this is the peak sync level). The 90% level is necessary to give some headroom for the 4.5 MHz sound subcarrier that is mixed and added with the video waveform. Once this peak sync level is set, use the blanking pedestal control to reduce amplifier output to 60% of this level. For example, a 100-W amplifier would first be set for 90 W with the RF power control and then 54 W with the pedestal control. Then the video can be plugged back in and the video gain adjusted for best picture.

If you could measure RF output with a peak-reading power meter made for video, the power would be between 90 and 100 W PEP. A dc oscilloscope connected to an RF diode detector in the antenna line shows that the sync and blanking pedestal power levels remain constant at their set levels regardless of video gain setting or average picture contrast. On an averaging power meter, however, it is normal with video to read about half the amplifier's rated power. The power reading will actually decrease with increasing video gain or with a change to a predominantly white picture. An averaging RF power meter cannot give an accurate measurement for an AM video signal given so many variables. If the amplifier drive level is properly set up according to the procedure outlined above, the actual sync tip PEP will remain constant.

Analog cable TV modulators can also be used to drive linear amplifiers, but most do not have adjustable sync stretchers. When driving an amplifier, the level must be kept below the upper nonlinear gain curve of the

**Figure 13 — An oscilloscope used to observe a video waveform. The lower trace is the video signal as it comes out of the sync stretcher. The upper trace is the detected RF signal from the amplifier.**

amp's output curve in order to maintain the proper video to sync ratio. The same is required when driving an amp from any low power ATV transmitter that does not have adjustable sync stretching. Most amateur amplifiers can be driven to their 1 dB gain compression output levels for ATV, which typically occurs around half the rated PEP output.

## 2.2 Frequency Modulated ATV

In Europe, FM ATV on the 23 cm (1240 MHz) band is the standard because there is little room for ATV in the amateur 70 cm band. In the US, AM on 70 cm remains the most popular ATV mode because of equipment availability, lower cost, less occupied bandwidth and use of a standard analog TV set for receiving. However, FM ATV is often used by repeater owners for links and alternate inputs.

As shown in **Figure 14**, FM ATV occupies 17 to 21 MHz depending on deviation and sound subcarrier frequency. While the 70 cm band is 30 MHz wide and thus theoretically could accommodate a 20 MHz wide FM ATV signal, the great interference potential to other users of the band precludes its use there. Most available FM ATV equipment is made for the 0.9, 1.2, 2.4 and 10.25-GHz bands. The 3.3 and 5.6 GHz amateur bands are also being explored by using C-band satellite receivers and converted Part 15 equipment.

The US standard for FM ATV is 4 MHz deviation with the 5.5-MHz sound subcarrier set to 15 dB below the video level. Suggested frequencies are 1252 or 1255 MHz to stay away from FM voice repeaters and other users higher in the band, while keeping sidebands above the 1240 MHz band edge. Using the US standard, with Carson's rule for FM occupied bandwidth (see the **Modulation** chapter), it comes out to just under 20 MHz — so 1250 MHz would be the lowest possible frequency. Check with local frequency coordinators before transmitting because the band plan permits other modes in that segment that may not be published.

C-band satellite TV receivers directly tune anywhere from 900 to 2150 MHz and may need a preamp added at the antenna for use on the 33 cm and 23 cm amateur bands. Early satellite TV receivers were made for antenna mounted LNBs (low noise block converters) with 40 dB or more gain. Satellite receivers are made for wider deviation (11 MHz) and need some video gain to give the standard 1-V P-P video output when receiving a signal with standard 4-MHz deviation. The additional video gain can often be had by adjusting an internal control or changing the gain with a resistor.

Some of the inexpensive Part 15 wireless video receivers in the 33 cm band use 4-MHz deviation FM video. Most of the 2.4-GHz Part 15 units are FM, so they can be used directly. On 2.4 GHz, some of the Part 15 frequencies are outside the ham band and care should be taken to use only those frequencies at least 8 MHz inside the 2390-2450 MHz ham band.

Part 15 receivers may or may not have the standard CCIR 405-1 de-emphasis video network, however, so some circuitry may have to be added. Video pre-emphasis in the transmitter and de-emphasis in the receiver can double the communication distance or give 6 dB of SNR improvement by reducing the receiver noise bandwidth. Coordination among local stations is needed, though, because you cannot match stations that have the networks with those that don't without distorting the video greatly. The sound subcarrier might also be on 4.5, 5.8, 6.0, 6.2, 6.5 or 6.8 MHz rather than 5.5 MHz. The FM sound deviation is 50 kHz.

## 2.3 Digital ATV

The greatest advantage to running digital ATV is that you have a perfect P5 picture all the way down to 15 dB (with 8-VSB) above the noise floor, and higher definition or more than one picture are possible in the same 6 MHz channel width used for analog AM ATV (see **Figure 15**). If you use the 40 dB signal-to-noise level at –61 dBm required to have snow-free ATV as a reference, DVB-T is 27 dB better than the 4 MHz deviation FM ATV and 39 dB better than analog AM ATV. This is a significant consideration for long-distance, point-to-point, line-of-sight paths and for paths requiring wide fade margins. Tuning in DTV requires greater accuracy and takes more patience if using a tunable down-converter. D-CATV QAM, for instance, at cable channel 58 on one TV needed to be tuned within 400 kHz but took a second or two within that range for the picture to appear. 64-QAM is much more resistant to interference than AM and stays P5 up to almost equal amplitude with another carrier.

DTV can send much more usable picture and sound information in the same bandwidth as analog AM ATV under the theory that you don't have to send a continuous serial stream of a scanned picture at 30 interlaced frames per second. Rather, in DTV you send one

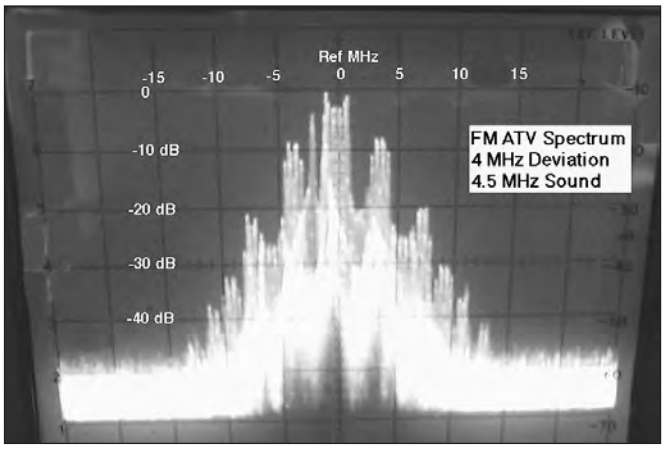

**Figure 14 — Spectral display of an FM ATV transmission using 4 MHz deviation with a 4.5 MHz sound subcarrier. (Note that 5.5 MHz is the standard and would be 2 MHz wider.) Occupied bandwidth as defined in FCC Rule 97.3(a)(8) is –26 dB down from the mean power points.**

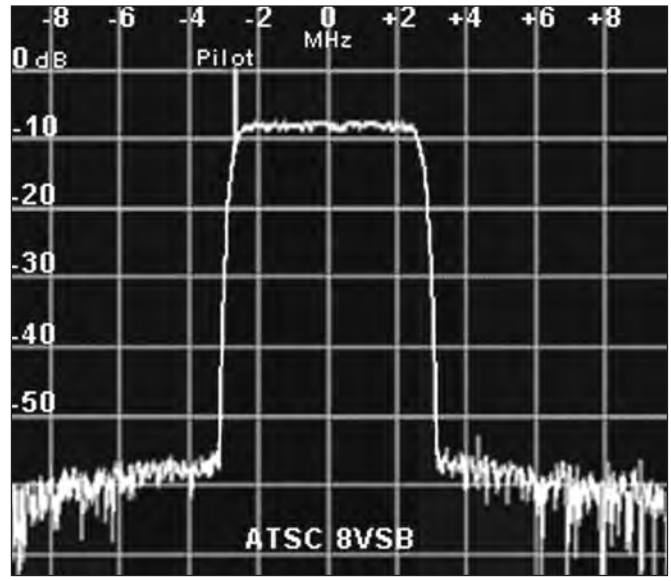

**Figure 15 — Spectral display of an ATSC 8-VSB digital TV transmission. Note the pilot carrier unique to this mode of DTV.**

whole frame and then send frames of only the changed pixels (or those pixels predicted to change, as explained in the next paragraph). Just the changes are sent a specified number of times (usually up to 15 times) before starting over again with a new complete frame.

There are complex algorithms based on how the human eye and mind perceive the picture as well as data compression techniques. For instance, there is the probability that a pixel or group of pixels that are moving in a direction on the screen will occupy the adjacent pixel location at a certain time. According to Henry Ruh, AA9XW (a longtime ATVer and retired Chief Engineer at WYIN-TV in Chicago), the coder/decoder (codec) software may expect a moving pool ball to continue in a straight line. If you watch closely, however, you may see the ball go deeper into the cushion than it really did until the next full frame. The bottom line is that the picture you see may be 10% actual data and 90% predictive algorithm for what your mind expects to happen.

## DIGITAL ATV TRANSMITTER REQUIREMENTS

DTV transmitters start with a modulator typically putting out around a milliwatt or 0 dBm followed by a series of very linear amplifiers, each of which is driven well below their 1 dB gain compression and low third-order intermod intercept points. A DVB-T modulator is quite complex and usually must be programmed with a PC computer if you want to change the factory settings, center frequency and add your call letters in as the Service Name for ID purposes. There are so many parameters that can be selected, that only programming from a computer is practical – hardly any knobs to adjust will be found. It is not unusual for the first ham on DATV in an area to program the modulator for each new ham coming on with the local frequency and parameters. The size of a DVB-T modulator can fool you given the level of today's IC miniaturization and software sophistication. Some are available as a USB dongle. **Figure 16** shows the spectral display of a 6 MHz DVB-T 8K QPSK signal.

Video input is typically an RCA phono jack or BNC for CVBS input. BNC may also be for analog high-definition cameras but most newer modulators use a HDMI jack for HD. DVRs and Adaptors for practically any camera video mode can be found to convert to HDMI. Modulators usually sense the type of video and automatically select the right parameters to encode.

DTV transmissions are rated at average power. With DVB-T modulation, the peak power is more than 6 dB greater than the average depending on the modulation parameters. DTV transmission requires an amplifier with high linearity and good IMD performance to prevent distortion, noise and spectrum sideband growth. For proper operation, amplifiers for DVB-T are generally run at ⅓ of its 1 dB gain compression level. For instance the KH6HTV video model 70-7B amplifier shown in Figure 4 is rated at 20 W FM or CW, 10 W AM ATV and 3 W DATV. These are rule of thumb levels with variations between devices. Lower transmit power levels are not as significant of a consideration with DVB-T as it would seem. As described earlier, DTV requires less signal strength than analog AM ATV to produce a P5 picture. Bipolar amps are rarely used, with the preference going to the power FET type of devices, such as LDMOS, with their better linearity and low IMD. Unless you have a spectrum analyzer to verify your amplifiers suitability and set up, it is best to stay with proven amplifiers for DATV. Since modulators take some time to load the firmware on power up, hams usually leave them on and switch the amplifier and antenna T/R relay on and off for transmit/receive. The amplifiers then need good input-to-output isolation when switched to off or standby in the receive state.

As can be seen in Figure 15, in an 8-VSB signal there is a pilot carrier 310 kHz up from the lower channel edge generated by a dc offset of the eight-level modulation. The pilot carrier has a tight tolerance of 3 Hz and gives the RF PLL circuits in the 8-VSB receivers something to lock onto that is independent of the data being transmitted. Unlike 8-VSB and DVB-T, DVB-S or D-CATV do not have a pilot carrier and requires less amplifier headroom (compare **Figure 17** to Figures 15 and 16).

With DTV, it's not good amateur practice to follow the ham tradition on other modes of increasing amplifier drive to the point that a receiver starts to break up and then back the drive down a little. Although increased transmitter IMD may not affect the received signal until the combination of the received signal-to-noise and the added transmitter amplifier noise reaches the cliff and the picture goes away, the generated sideband levels can be quite large and interfere with other users on adjacent frequencies.

An analog VSB 6 MHz bandpass filter in the antenna line can help keep the unwanted

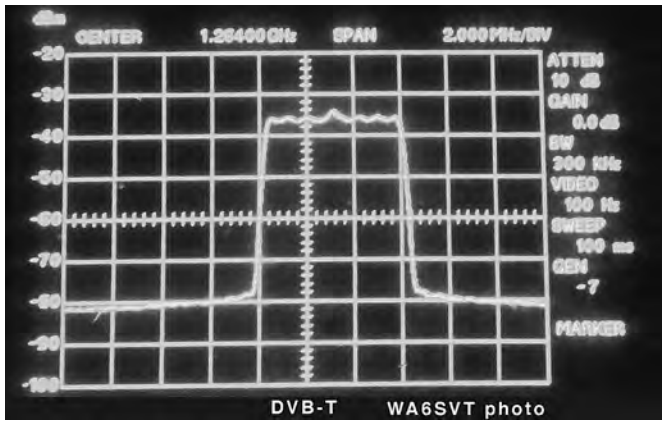

**Figure 16 — Spectral display of a 6 MHz DVB-T 8K QPSK signal from the modulator used at the WA6SVT repeater. The "Haystacks" of DVB-T, DVB-S and cable 64-QAM are similar, but DVB-T has a center pilot carrier that can be seen. While not apparent, the peak to average power difference can be as much as 15 dB. This 8K QPSK DVB-T signal actually has 6817 carriers spaced 837 Hz apart.**

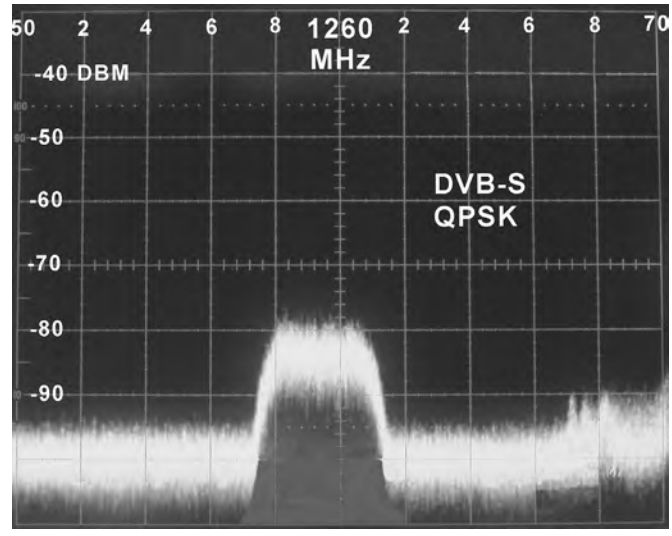

**Figure 17 — A DVB-S QPSK signal from the WR8ATV repeater output as received on a spectrum analyzer. Note that the average power appears to be not too far above the noise floor, but gives a P5 picture. P units are measures of picture quality from P1 to P5 with P5 being the clearest and best picture.**

**Figure 18 — Mobile ATV as shown here with a portable TV works fine using D-CATV 64-QAM, but it exhibits occasional freeze or tile effect from drop outs and multipath.**

**Figure 19 — Art Towslee, WA8RMC, in his shack transmitting QPSK DTV through the local ATV repeater in Columbus, Ohio.**

sideband growth down. As can be seen in Figures 15, 16 and 17, DTV spectrum power density is high across the whole channel width and will show up as noise in a narrowband receiver tuned within the 6 MHz channel. For this reason, DTV running any significant power from an amplifier, should be used in the higher bands or 420-431 MHz segment of the 70 cm band so as not to interfere with FM voice repeaters, weak signal modes and satellite work. However, those areas that use AM video carriers of 434.0 or 439.25 might be able to use 2 MHz DVB-T centered at 434.0 and 439.0 to avoid significant energy in the satellite and FM voice repeater segments. Check your local band plan. Modulators need to be selected that will generate 2 MHz modulation and are harder to find. 6, 7 and 8 MHz are the norm.

DVB-T with 2, 4 or 6 MHz bandwidth can use the same channel as AM ATV, but the spectrum power density is relatively flat across the bandwidth and care must be taken with amplifiers to keep sideband growth down below 30 dB and within the channel. DTV frequency is specified as the center of the occupied bandwidth. For instance, the channel for an AM ATV carrier at 421.25 would go from 420.0 to 426.0 MHz. A DVB-T transmission running 6 MHz bandwidth in the same channel would be described as running at 423.0 MHz. The operating frequency is not generally shown on the front panel, but rather a channel number that is user programmed.

## DTV ISSUES

Latency - The DVB-T digital processing takes time at both ends, which can vary with the type, bandwidth and other parameter modulator settings. The higher the desired picture resolution, the higher the required bandwidth and results in longer latency. Delays can typically be anything from .5 to 5 seconds depending on the speed of the codec processors. System latency can be measured as shown in **Figure 20** by aiming the camera at a clock and snapping a photo with a digital camera of the clock and the system video monitor to get the difference in time. It takes some getting used to the wait for another station to respond back to you if running duplex ATV or talking back on 2 meters, especially if using a DTV in/out repeater where the latency will be double that of simplex. It also takes time for the DVB-T receiver to sync up and lock on to the new signal after another station starts transmitting. These delays can vary from tenths of a second to many seconds. Power up delays can take as much as a half minute with modulators and 10 seconds for receivers. For this reason, both are typically left powered on, and only the linear amp and antenna relay are switched between transmit and receive. Linear amplifiers and T/R antenna relays totaling in the order of 100 dB isolation in receive must then be used to keep the modu-

**Figure 20 — An indication of system latency can be determined by aiming the video camera at a digital clock, in this case a count-down from the internet with milliseconds, and shooting a photo with a digital camera of both the clock and receive monitor to compare the times. Here, total delay through a DVB-T modulator and receiver running 2 MHz bandwidth with a CVBS 480i camera is about ½ second.**

lator from interfering with the receiver.

Delays make it more difficult to aim and focus the cameras if monitoring your own video. Camcorders are preferred for DATV as they have a real time monitor built in and most current ones have the HDMI output for direct connection to monitors and DVB-T modulators.

With Broadband-Hamnet, the latency will vary by the processing time of the computer and its application used to see the video, system loading, number of nodes and bandwidth. An experiment using the latency test outlined above showed even with a direct connection using an Ethernet crossover cable between an IP Camera and a computer, processing speed makes a big difference. A 2008 MacBook had a delay of 3.4 seconds and a 2014 Mac Mini only 0.4 seconds.

Controlling an R/C vehicle can be more challenging with DATV vs. AM or FM ATV because of latency. Weight and battery life is another factor.

Standardization – The cost, complexity and availability of gear to set up a DATV station has slowed the development of which way to go among the DTV modes until recently. DVB-T seems to have the most benefit for hams vs. the other DTV modes. It has the best distance and performs well with multipath and motion. Set top boxes for receiving DVB-T can be found on the internet for reasonable cost. However, these do not do 2 or 4 MHz bandwidth and do not tune the 70 cm ham band directly, requiring a downconverter. But there are a few sources of receivers and transmitters aimed for the ham radio market such as HI-DES (**hides.com.tw**) and KH6HTV VIDEO (**kh6htv.com**). DATV-Express (**datv-express.com**) has an assembled board level exciter/transmitter with software. So far, they still require the user to program the modulator with a computer or scan an active channel into memory to receive. See Application Note AN-18B at **kh6htv.com/application-notes** on setting up the Hi-Des modulator and receiver. A local DATV Elmer or source willing to supply them ready to go set up on your local frequency can be a big factor in getting on DATV. DVB-T modulators send a Packet Identification number (PID) in its data transport stream that is used by stations to tell the receivers to recognize only their station or program on a channel. It is similar to CTCSS with FM voice. All hams in an area need to have the same video PID number – 641 is suggested.

The current recommended setup for DVB-T modulator ATV is:

*Modulation*: 6 MHz bandwidth, Constellation QPSK, FFT: 8K, FEC code rate: 7/8, Guard Interval: 1/16, Max Data bit rate: 5856 kbps, PMT PID: 640, Video PID: 641, Audio PID: 642, Network, Service and Provider Name: your call letters.

*Video source*: Camcorder with HDMI plug, 1080p resolution, H.264, 16:9 aspect ratio.

## 2.4 ATV Antennas

Foliage greatly attenuates signals at UHF, so place antennas above the treetops for the best results. Beams made for 432 MHz SSB/CW work or 440 MHz FM may not have enough SWR bandwidth to cover all the ATV frequencies for transmitting, but they are okay for reception. A number of manufacturers make beam antennas designed for ATV use that cover the whole band from 420 to 450 MHz. Use low-loss feed line and weatherproof all outside connectors. Almost all ATV antennas use N connectors, which are more resistant to moisture contamination than other types. See the **Transmission Lines** and **Component Data and References** chapters for help with appropriate cable and connectors.

Antenna polarization varies from area to area. It is common to find that the polarization was determined by the first local ATV operators based on antennas they had in place for other modes. Generally, UHF/microwave operators active on SSB, CW and digital modes have horizontally polarized antennas, while those into FM, public service or repeaters have vertical antennas. Check with local ATV operators before permanently locking down the antenna clamps. Circularly polarized antennas let you work all modes, including satellites and have less multipath effects.

## 2.5 ATV Identification

ATV identification can be on video or the sound subcarrier. A large high-contrast call-letter sign on the wall behind the operating table in view of the camera is the easiest way to fulfill the requirement and more easily recognized (see **Figure 21A**). Transmitting stations fishing for DX during band openings often make up call sign IDs using fat black letters on a white background to show up best in the snow. Their city and 2 meter monitoring frequency (typically 144.34 or 146.43 MHz) are included at the bottom of the sign

(A)

(B)

**Figure 21 — At A, the simplest video identifier is to draw your call sign on a piece of paper and put it on the wall of your ham shack and in view of the camera. Doug Moon, K6KMN, also has his old auto call letter license plate as his ID. At B, the call sign, event name and location are overlaid on the video. During a public service event such as a long trail running race it is easy to forget to ID especially if operating full duplex and a lot is going on. See www.foothillflyers.org/hamtvac100.html for a description of ATV at the Angeles Crest 100 Mile Trail Race.**

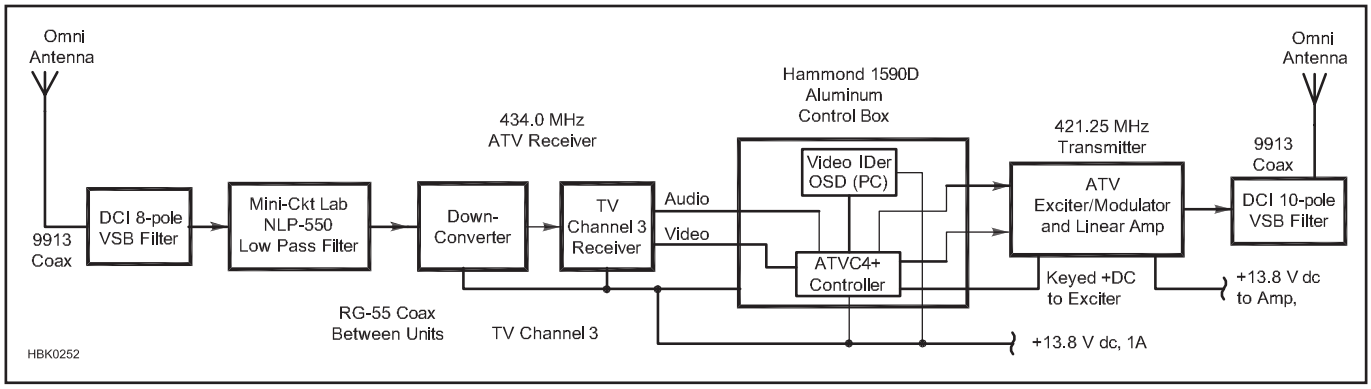

**Figure 22 — A block diagram of a 70 cm in-band ATV repeater. The omnidirectional antennas are vertical and require 20 feet (minimum) of vertical separation to get >50 dB isolation to prevent receiver desensitization. Horizontal omnidirectional antennas require much more separation. A low-pass filter on the receiver is also necessary because VSB or cavity type filters repeat a pass-band at odd harmonics and the third-harmonic energy from the transmitter may not be attenuated enough. While AM ATV is shown, other modes and bands can be substituted. Video ID can be done with a video overlay board like the Intuitive Circuits model OSD-ID+ — by itself or even overlaid on a tower cam. The Intuitive Circuits ATVC-4+ ATV repeater controller board can do all the control box functions as well as remotely select from up to four video sources such as links.**

to make beam alignment and contact confirmation easier. With DVB-T and Broadband-Hamnet video, the call can be programmed into the digital address header as the Service Name which is continuously sent.

Quite often the transmission time exceeds 10 minutes, especially when transmitting demonstrations, public service events, space shuttle video, balloon flights, or from a recording. Intuitive Circuits makes a variety of boards that will overlay text on any video looped through them. Call sign characters and other information can be programmed into the board's nonvolatile memory by on-board push buttons or an RS-232 interface from a computer (depending on the version and model of the board). See Figure 21B. One model will accept NMEA-0183 standard data from a GPS receiver and overlay latitude, longitude, altitude, direction and speed, as well as call letters, on the applied camera video. This is ideal for ATV rockets, balloons and R/C vehicles. The overlaid ID can be selected to be on, off or flashed on for a few seconds every 10 minutes to automatically satisfy the FCC ID requirement. The Intuitive Circuits ATVR+ ATV repeater controller board has an automatic nine-minute timer, and it also has an end-of-transmission hang timer that switches to another video source for ID.

## 2.6 ATV Repeaters

There are two kinds of ATV repeaters: in-band and cross-band. In-band repeaters for 70 cm are more difficult to build and use, yet they are more popular because equipment for that band is more available and less expensive. Some ATV repeaters have added streaming video of their outputs to the Internet so users can see when they are active. Some repeaters even use the Internet to establish links. A good number of US repeaters can be found on the **www.batc.tv** Streaming Members Web site and some accept check-ins during nets.

Why are 70 cm ATV repeaters more difficult to build than voice repeaters? The wide

**Figure 23 — At left, an ATV repeater "tower cam" IDs have become popular so that users can see approaching weather. Some cameras have remote pan and tilt, so users can observe ice build-up on antennas or activity at the repeater site. At right, Roland KC6JPG. who loves playing with video overlays and graphics, conducts the Tuesday night net through the ATN (Amateur Television Network) hub repeater on Santiago Peak. Check-ins are on the air from eight linked repeaters in three states. Inputs vary using AM. FM and DVB-T. Grant, VK3XTV, who sometimes checks in from Melbourne Australia via the BATC streaming video on the Internet, was in the states visiting Mike, WA6SVT.**

bandwidth of ATV makes for special filter requirements. Response across the 6-MHz passband must be as flat as possible with minimum insertion loss, but response must sharply roll off to reject other users as close as 12 MHz away. Special 6 to 10 pole interdigital or combline VSB filters are used to meet the requirement. An ATV duplexer can be used to feed one broadband omnidirectional antenna, but an additional VSB filter is needed in the transmitter line for sufficient attenuation to keep noise and IMD product energy from de-sensing the receiver. The receiver and possibly the transmitter might also need a low-pass filter to attenuate the third harmonic which can pass through a VSB or band-pass filter with little attenuation and overload the receiver front end.

A cross-band repeater requires less sophisticated filtering to isolate the transmitter and receiver because of the great frequency separation between the input and output. No duplexer is needed, only sufficient antenna spacing or low pass and/or high pass filters. In addition, a cross-band repeater makes it easier for users to see their own video. Repeater linking is easier too, if the repeater outputs alternate between the 23 cm and 33 cm bands. Wide-area linking has been done using the 2.4, 3.4 and 5.6 GHz bands using modified Part 15 FM transmitters with amplifiers or streaming video from the internet. Six ATV repeaters in Southern California are linked to one in Las Vegas NV and another in Mesa AZ (See **Figure 23A**).

### A 70 CM ATV REPEATER

**Figure 22** shows a block diagram for a simple 70 cm in-band analog AM ATV repeater. No duplexer is shown because the antenna separation (>50 dB) and VSB filters provide adequate isolation.

To prevent unwanted key up from other signal sources, ATV repeaters use a video operated relay (VOR) in the controller. The VOR senses the horizontal sync at 15,734 Hz in much the same manner that FM repeaters use CTCSS tones. Just as in voice repeaters, an ID timer monitors VOR activity and starts the repeater video ID generator every nine minutes, or a few seconds after a user stops transmitting. A tower-mounted camera is often used in place of a video ID generator at repeaters (see Figure 23B).

The repeater transmitter power supply should be separate from the supply for the rest of the equipment. With AM ATV the current varies greatly from maximum at the sync tip to minimum during white portions of the picture. Power supplies are not generally made to hold tight regulation with such great current changes at rates up to several megahertz. Even the power supply leads become significant inductors at video frequencies. They will develop a voltage across them that can be transferred to other modules on the same power supply line.

# 3 ATV Applications

## 3.1 Public Service

Live video from an incident site back to an Emergency Operations Center (EOC) is a valuable addition to disaster communications. A real-time view of the incident scene can give commanders an immediate feel for the overall picture of what is going on or zoom in on a critical component rather than rely solely on descriptions relayed by voice or data. While ATV has cut down the voice traffic repeats and clarifications, it has the added benefit of full duplex audio. The ATV transmitting station in the field talks on the sound subcarrier and the EOC can talk back at the same time on 2 meter FM voice. Races, parades and other public service events benefit from a ham volunteer transmitting video back to medical and emergency response personnel of what is happening at a critical street corner or incident as shown in **Figure 24**. See how to put together a portable ATV transmitter in a belt pouch at **www.hamtv.com/atvpouch.html** and on page 1.70 of the 11th edition of the *ARRL Operating Manual* for radio amateurs. A camera and transmitter can be mounted on a robot and sent into a hazardous situation with no risk to people. The BCARES AREC group in Colorado has put together a high definition DVB-T transmitter system in a backpack for emergency communications and public service events – See the referenced article by Jim Andrews, KH6HTV. Broadband-Hamnet is being developed and installed with nodes at high locations to serve the emergency communications needs of an area. Besides voice and data they can stream video similar to SKYPE but using the ham bands.

### AN ATV "GO KIT"

Communications "Go-Kits" are popular with ARES and RACES groups. When an emergency occurs, hams can just grab their kit and go out in the field with everything they need. Nick Klos, AC6Y, put together three ATV Go-Kits for the police department ARES group in Corona, California. See **Figure 25**. Each kit uses an easy-to-transport

**Figure 24 — A low power 50 mW battery operated portable 70 cm AM ATV transmitter is ideal for short range line of sight paths of up to 2 miles using 5 element beams. This setup can be used to show a critical intersection or condition of runners as an early warning to emergency response and aid station volunteers at races.**

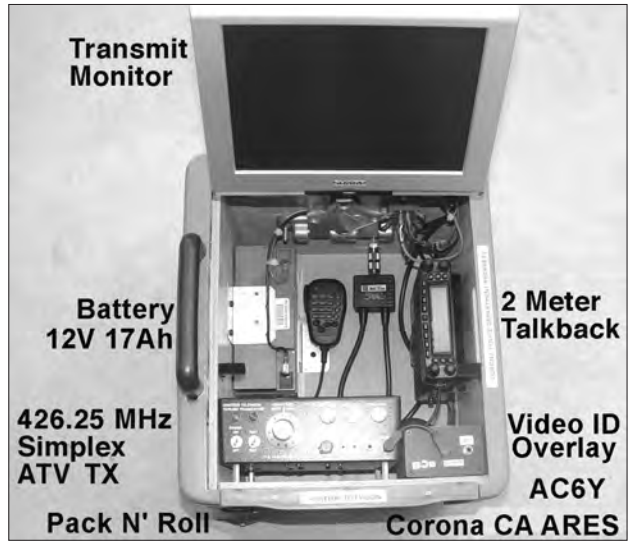

**Figure 25 — This portable ATV Go-Kit for emergency and public service work was built by Nick Klos, AC6Y. It includes a 70 cm ATV transmitter, 2 meter FM transceiver and battery in a Pack N' Roll container.**

Pack-N-Roll enclosure. (Pack-N-Rolls come in various sizes, have wheels, and have an extendable handle similar to airline carry-on luggage.) The ATV transmitter, 2 meter transceiver, battery and optional video monitor are fastened to plywood cut to fit the inside of the enclosure. A dc power supply can also be added if ac is available, or power can come from a dc extension cord with clips to connect to a car battery.

If the distance to be covered is short enough, a 2 meter/70 cm dual-band mobile vertical antenna connected through a duplexer and mounted on at least 10 ft of TV mast above the Go-Kit is sufficient for communication with a mobile command post. Longer or obstructed paths between the incident site and the EOC may require beams and more antenna placement care.

Multiple ATV Go-Kits allow for views of an incident site from different perspectives, including the police department helicopter and mobile or portable stations on the ground. The Go-Kits can also be used for parades, running and bike races, which are good operational practice for when the real emergency might happen.

## PORTABLE REPEATERS

A portable ATV repeater for public service events can also be built in a Pack-N-Roll enclosure or a milk crate for easy transport and set up on the top of a building or hilltop by car or even helicopter. The path between an ATV station in the field and the EOC is rarely line-of-sight, so the portable ATV repeater can be placed at a high point that can be accessed from both locations.

The portable repeater shown in **Figure 26** is a cross-band unit with 70 cm input and 23 cm output. By using 70 cm input to the repeater, you get the best distance for the lowest power by those moving around an incident site with hard-hat cameras or portable units. Another advantage to using low-in and high-out at the repeater is that filtering is much easier because you don't have to contend with strong repeater transmitter harmonics in the receiver. Antenna separation of 5 ft is usually enough running a less than 5-W, low-in/high-out portable repeater.

With weaker signals, a low-pass filter in the 70 cm receiver feed line and a high-pass filter in the 23 cm transmitter feed line may help to minimize desense. If a portable ATV repeater system is used at or near a communications site, band-pass filters in the antenna feed lines should be used to prevent intermodulation interference or receiver overload from nearby transmitters.

With compact 10-dBd gain corner reflectors or higher gain beams on 23 cm, you can get more than 5 miles line-of-sight from the repeater to the EOC with just 3 W of transmit-

(A)

(B)

(C)

**Figure 26 — At A, Tom O'Hara, W6ORG, adjusts a portable ATV repeater for public service work that can be built in a milk crate. The block diagram is similar to Figure 14 but without the VSB filters. The transmitter is a PC Electronics RTX23-3 on 1253.25 MHz, the receiver is on 426.25 MHz, and small beams or omni antennas are used. For more details on construction, visit www.hamtv.com/info.html#portrpt. At B, the repeater is flown to a hilltop and quickly set up. Sharon Kelly, KF6OQO, is adjusting the antenna. At C, the video of a fire can be seen at an EOC on the other side of the hill while Gary Heston, W6KVC, talks back to the incident site ATV operator on 2 meters.**

ter power. The portable repeater shown is self-contained with a 12-V, 17-Ah battery that will last about 12 hours. Alternatives include ac-operated 13.8 V, 3 A power supply or a dc cord clipped to a car battery. A local camera can be plugged in and used if needed. Details of the milk crate repeater can be found at **www.hamtv.com/info.html** under Portable Public Service Repeater.

## 3.2 Radio Control Vehicles

Some hams also enjoy operating radio control (R/C) vehicles, and ATV can add a new dimension to that hobby. The size, weight and cost of color cameras have come way down, and ATV transmitters are smaller as well, so ATV stations can more easily be integrated into R/C vehicles to give them eyes and in some cases ears. Quadcopters and drones with video have become popular and some are on shared Part 15 frequencies in the higher ham bands.

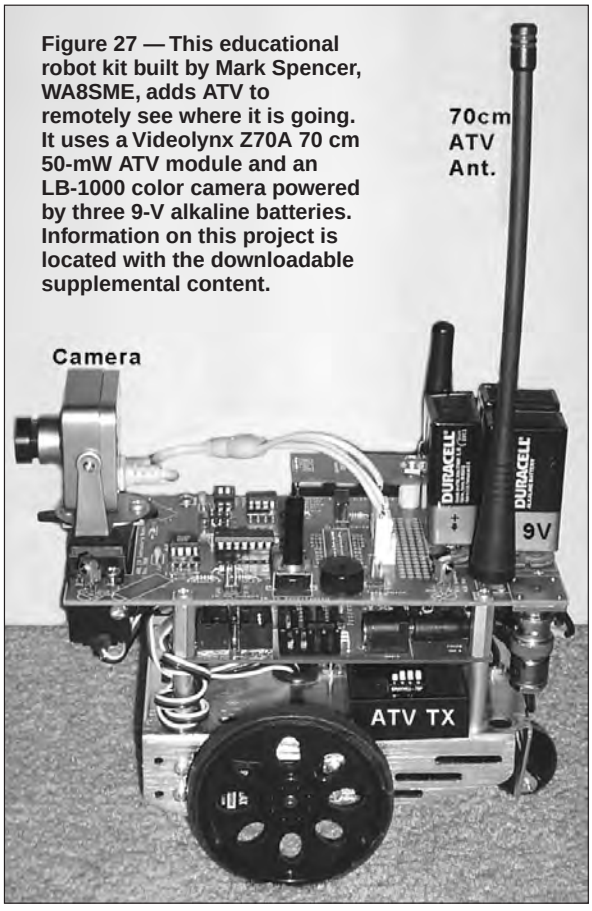

**Figure 27 — This educational robot kit built by Mark Spencer, WA8SME, adds ATV to remotely see where it is going. It uses a Videolynx Z70A 70 cm 50-mW ATV module and an LB-1000 color camera powered by three 9-V alkaline batteries. Information on this project is located with the downloadable supplemental content.**

### AN EDUCATIONAL TOOL

Mark Spencer, WA8SME (ARRL Amateur Radio Education and Technology Coordinator) added ATV capability to a Parallax Board of Education Robot (BOE/BOT) as shown in **Figure 27**. With the add-on ATV board, the BOE/BOT simulates a Mars Lander. The robot and ATV board are also used to teach students how a TV remote control works, as well as demonstrate remote sensing and data linking. This ATV application has encouraged students to use the kit as a science class project and become licensed hams in the process.

### R/C VEHICLE TIPS

ATV and data transmitter modules have been put in R/C aircraft, blimps, cars and boats. A Videolynx 434 50 mW transmitter on 70 cm is enough to give good video for ½ mile or so around an R/C flying field. An inverted ground-plane or vertical dipole is used typically on aircraft, but nulls in the radiation pattern can show up at steep bank angles. Ground-plane antennas are also used for receive because the pattern is broad. Mounting the receive antenna at least 10 ft above ground can help avoid multipath ghosting or signal blockage from nearby people and vehicles. Use of higher gain omnidirectional antennas is tempting for greater distance, but they have narrower radiation patterns and more nulls.

Operation at higher frequencies requires shorter antenna lengths that might better fit the physical size limitations of an R/C vehicle, but snow-free distance will be shorter given the same transmitter power and receive antenna gains.

If ac power is not available at the flying field for plugging in a TV, look for a portable television that can be powered from batteries. Some hams have used TV tuners designed for use with laptop computers. Position the screen to be north facing for least sun washout. It is best for even experienced R/C operators to not fly solely by video, but to have a copilot observe directly as the camera's field of view is limited.

Typical 72 MHz or 50 MHz R/C receivers are not designed to operate with a transmitter in the same vehicle. The R/C receiver front end could overload from ATV transmitter RF, so control distance testing is a must before

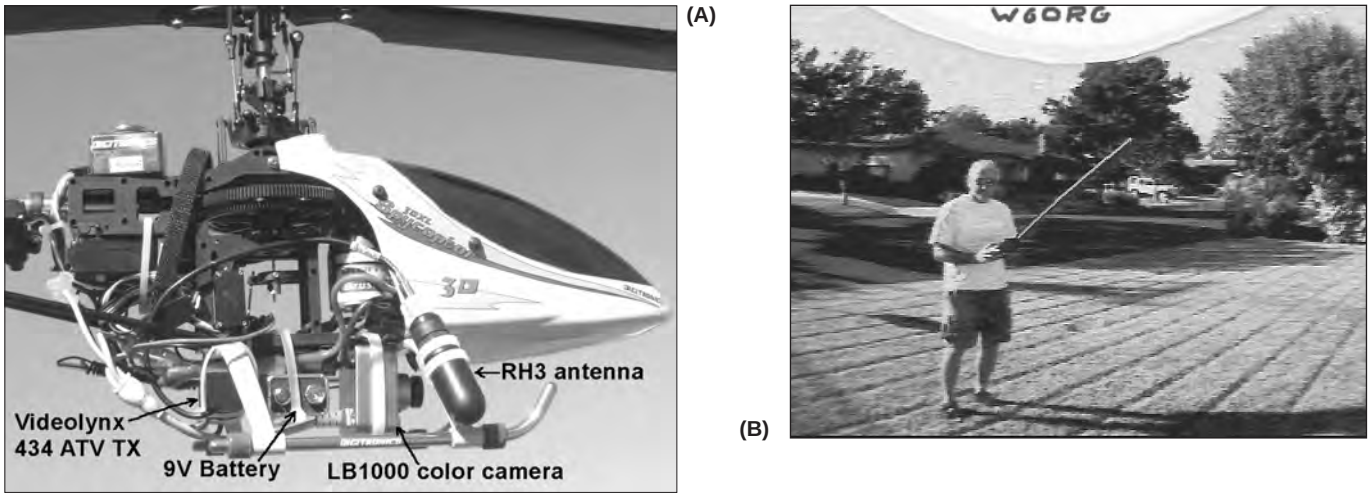

**Figure 28 — At A, cable ties are used to fasten an LB-1000 color camera, Videolynx 434 ATV transmitter, 9 V battery and Diamond RH3 antenna to an R/C helicopter powered by an electric motor. At B, a computer with a TV tuner plugged into the USB port is used to view video coming from the ATV transmitter on the R/C helicopter — in this case, looking back at the R/C model operator.**

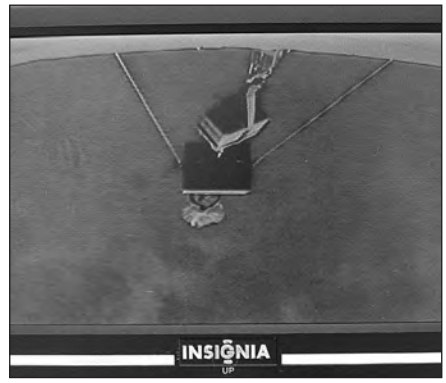
the first flight. Testing can be done by having another ham (with a handheld radio for talk-back) carry the R/C vehicle out to the normal limit of control distance. Then turn on the R/C transmitter and verify that the controls are working normally. Finally, turn on the ATV transmitter and again verify operation.

If the R/C receiver is captured by the ATV transmitter, then experiment with lowering power, changing antenna placement, or adding shielding or filtering. In the past, crystal oscillator leakage was often the culprit, rather than the 70 cm output, and could be cured by Shielding. Interference may be less of a problem with a newer ATV transmitter that uses a PLL oscillator.

### A PRACTICAL EXAMPLE



The added weight of the ATV system on the electric R/C helicopter shown in **Figure 28** is only 7 oz, but first you need to determine that the craft can lift the added load. The extra equipment must be mounted to maintain balance around the aircraft's center of gravity. Some testing with equivalent weights first can save equipment from possible damage. Note the stubby flexible antenna mounted upside down on one of the skid supports. This is counterbalanced by mounting the R/C receiving antenna on the opposite side.

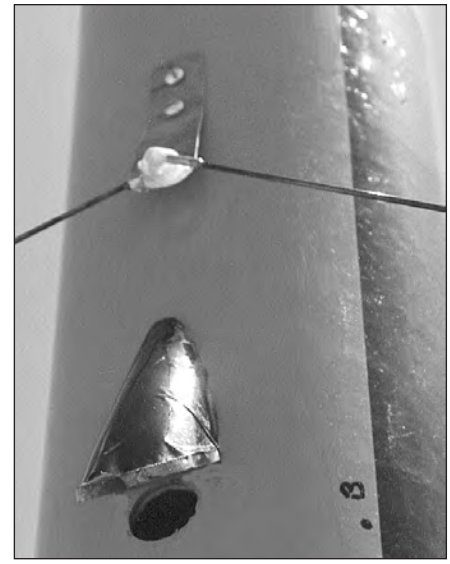
A separate battery should be used for the ATV system rather than tapping into the motor or R/C receiver battery. The voltage will vary during the flight and could put motor noise in the video. A standard 9 V alkaline battery will last almost two hours continuous duty with this system.

On larger R/C aircraft having sufficient payload, a GPS receiver and Intuitive Circuits video overlay board can put the speed, altitude and direction, along with call sign, over the camera video.

(A)

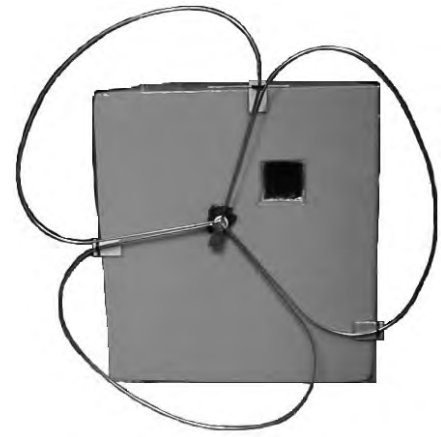
(B)

**Figure 29 — At (A), an ATV camera view from a balloon at 93,399 feet shows the blackness of space, the curvature of the earth and hazy clouds below. Note that the standard NMEA altitude data output from GPS receivers is in meters. At (B), video received from a balloon on a 7 inch portable LCD TV at 20 miles slant distance. The camera is looking down at the instrument package, with clouds and the ocean below.**



## 3.3 ATV from Near Space

Seeing the earth fall away via ATV as an amateur rocket or balloon rises can be quite exciting as shown in **Figure 29**. There are a number of groups sending up balloons and rockets with instrumentation, beacons and repeaters in addition to ATV. Balloon transmissions have been received as far as 500 miles away as the instrument package rises to 100,000 ft before the balloon pops from gas expansion and ultra violet decomposition and then parachutes back to earth. Radio direction finding clubs are often asked to help find where the balloon has come down and aid in recovery.



Rockets and balloons using ATV present a challenging optimum antenna radiation pattern problem similar to satellites that are predominantly flown overhead. For strongest picture and best distance (DX), the transmit and receive antennas should have their major power lobes pointed at each other and use the same polarization.

An omnidirectional vertical dipole antenna in the vehicle is fine for best DX on the horizon where the receiving station views the vehicle from a low angle. For example if a rocket is expected to go 1 mile vertically, receiving stations at 4 miles or more away will be within the maximum radiation lobe of the antenna and get the best video. Receiving stations at the launch site or closer than 4 miles away would be within pattern nulls.

If the rocket antenna is a 1/4 wave vertical spike on the nose and the body of the rocket is the ground plane, the main lobe can have an up-tilt of 15 to 20° above the horizon and a significant amount of the signal will be wasted. Balloons can use an upside down ground plane hanging below the instrument

(A)

(B)

(C)

**Figure 30 — At (A), a dipole antenna and a mirror are mounted on the outside of a 3.5 inch diameter amateur rocket. A video camera inside looks through the hole to the mirror so those receiving can see the view of the ground fall away as the rocket blasts off. At (B), N8UDK mounted an Old Antenna Lab 70 cm Little Wheel horizontal omni antenna to the bottom of his high-altitude balloon ATV payload. The camera is mounted inside the insulated foam package and looks out through the square cutout. At (C), a handheld antenna using circular polarization can be pointed at a balloon or rocket for maximum signal level as it travels. See www.hamtv.com/rocket.html.**

package to give a down tilt to the earth below.

At the launch site, a horizontal dipole on the rocket (see **Figure 30)** and circularly polarized antenna on the ground works best. Balloons do well by hanging down an omnidirectional wheel antenna that is horizontally polarized on the horizon, but circularly polarized directly below. Circular polarization at one end helps to minimize the signal strength variation as the vehicle spins.

An adjustable power 5-W, 70 cm ATV transmitter module such as the Videolynx VM-70X is a good tradeoff between power and battery weight. Balloon flights are typically over many hours and the temperature and heat dissipation vary greatly. A 50K thermistor is added to the VM-70X at the RF Power adjust pot trace to ground to reduce the power when the module gets too hot, but brings it back up in the cold altitudes. A beam antenna for reception is necessary to make up for the low power if you want snow-free pictures from higher than 20,000 ft. Typically, ATV equipment is housed in an insulated enclosure suspended below the helium-filled balloon, along with a battery capable of lasting the expected length of flight time. Styrofoam is light and will retain some of the heat dissipated from the electronics so that the extreme cold at altitude does not cause the transmitter and battery to cease operation. However, the heat from the ATV transmitter needs to be partially ducted outside the foam package with a sheet of copper. See the **Telemetry and Navigation** chapter for more information on balloon platforms.

Balloon and rocket groups have a lot of how-to information and often announce when there will be a launch so that hams within a few hundred miles radius can try receiving the signals. Some groups are:

# 4 Video Sources

Practically any video device that delivers a picture when plugged into the coaxial video jack of a video monitor can be plugged into an ATV transmitter and used to send video over the air. Suitable sources include the composite video from camcorders, video cameras, digital cameras, VCRs or computers. The standard A/V cable from a video device has a phono plug on the end and is often identified by yellow color coding (other colors are used for audio).

The cost of video cameras has come way down, thanks to the development of solid state imaging devices that vary in size, type and number of horizontal and vertical picture elements (pixels). Cameras widely available for home video work well for ATV.

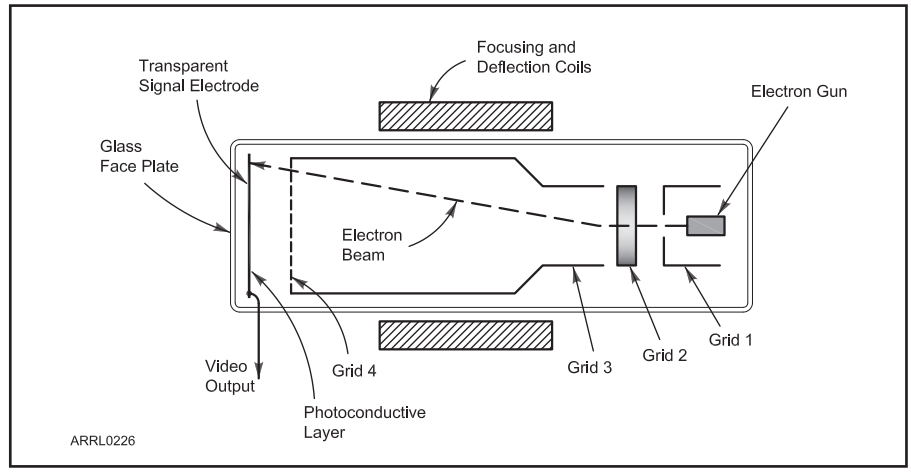

**Figure 31 — The construction of a vidicon tube used for acquiring video images. Light striking the front of the tube causes the current in the electron beam from the cathode to photoconductive layer to change. These changes create the electronic video signal.**

## VIDICON TUBES

The vidicon is a relatively simple, inexpensive vacuum tube imaging device that once was the standard for home video cameras, closed-circuit television and ATV applications. **Figure 31** shows a vidicon's physical construction. As with a cathode ray tube (CRT), an electron beam is created by a cathode and accelerated by grids. Horizontal and vertical deflection of the electron beam in a vidicon is accomplished with magnetic fields generated by coils on the outside of the tube. Varying the strength of the fields control the beam's position as it scans across the inside of the front of the vidicon, which is coated with a photoconductive screen layer. As the electron beam scans the screen, it charges each spot on the screen to the cathode voltage (about –20 V with respect to the signal electrode). Each spot acts like a leaky capacitor, discharging when illuminated by light hitting the front of the vidicon. The rate of discharge depends on the intensity of light illuminating the spot.

When it next scans across the spot, the electron beam will deposit enough electrons to recharge the spot to cathode potential. As it does so, the current flowing between the cathode and the screen increases, proportionally to how much the spot's "capacitor" discharged since last being scanned by the beam. Since this discharge depends on the amount of light hitting that spot on the screen, the changes in the beam current as it scans the screen correspond to the image being viewed by the screen. This creates a video signal that represents the scanned image. The variations in the beam current are very low (a fraction of a microamp), and the output impedance of the vidicon is very high, so the video circuitry must be designed with care to minimize hum and noise and the tube itself must be carefully shielded.

## CHARGE-COUPLED DEVICES

A *charge-coupled device (CCD)*, in its simplest form, is made from a string of small capacitors with a MOSFET on its input and output. The first capacitor in the string stores a sample of the input voltage. When a control pulse biases the MOSFETs to conduct, the first capacitor passes its sampled voltage on to the second capacitor and takes another sample. With each successive control pulse, the input samples are passed to the next capacitor in the string. When the MOSFETs are biased off, each capacitor stores its charge. This process is sometimes described as a "bucket brigade," because the analog signal is sampled and then passed in stages through the CCD to the output.

**Figure 32** shows a two-dimensional CCD

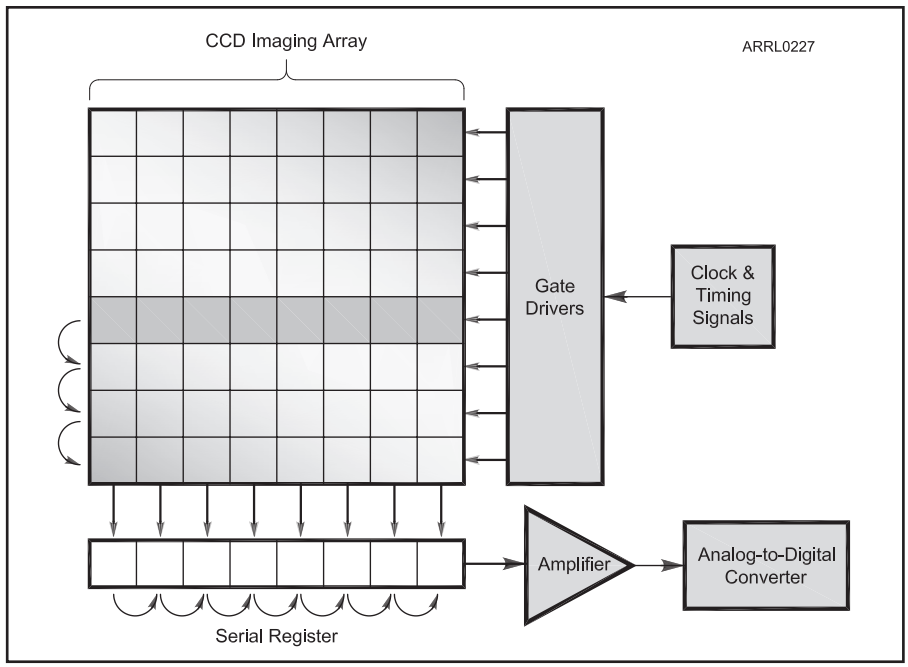

**Figure 32 — The construction of a two dimensional CCD array that might be used in a digital camera. When a control pulse biases the array to conduct, the first row passes its sampled voltage on to the next row and takes another sample. With each successive control pulse, the input samples are passed to the next row until they reach the edge of the array. There they are transferred to a serial register and digitized**

**Figure 33 — Michael Saculla, K6MDS, built an ATV Hat Cam — www.hamtv.com/hatcam.html — using a CMOS color camera along with a Videolynx 70 cm transmitter for public service applications.**

that might be used in a digital camera. In a CCD used for imaging, an array of sensing elements called *pixels* are coated with light-sensitive material. The light-sensitive material in each pixel *photocharges* a single CCD capacitor. The photogenerated charge on each capacitor is proportional to the amount of light striking the sensing element. The stored charges are then shifted out of the CCD array a line at a time as signals corresponding to each pixel. The resulting sequence of signal is similar to that of a vidicon scan. CCDs are the most common imaging device used in digital photographic cameras as well as video cameras, and they have very good low-light sensitivity.

Color CCDs use a screen, called a Bayer mask, over each square of four pixels. Each square has one for red, one for blue and two for green because the human eye is more sensitive to green. The luminance — gray scale — is sampled from every pixel. The possible lines of vertical resolution are determined by the number of pixels horizontally, but color resolution will be less because it comes from a square of four pixels.

When *lines of resolution* are given for a camera, this refers to the number of changes from vertical black lines to white that can be seen horizontally across the picture. While it is good to have a higher resolution camera — most are 380 lines or more — the picture will still be seen on a TV or monitor. In these display devices, response bandwidth limits luminance to about 240 lines and color to 100 lines in the NTSC system.

## CMOS CAMERAS

CMOS active pixel sensors are a newer development and are replacing CCDs in imaging products. CMOS cameras have lower current requirements, lower price and less image lag, making them popular in cell phones. Amateurs use them for portable ATV applications such as the hat cam in **Figure 33**. A small CCD color camera may draw 120 mA while a comparable CMOS version draws 50 mA.

At first glance, board-level cameras are lighter for weight-sensitive applications like R/C and balloon vehicles, but those housed in a metal case are preferred to afford shielding from the effects of RF getting into the circuitry. The CMOS camera shown in **Figure 34** only weighs 3 oz in a 1.5-inch square metal case. It also includes a mic with line level audio output.

**Figure 34 — The tiny LB-1000 420-line CMOS color camera is typical of the many low-cost devices available. Intended primarily for security applications, they are popular with amateurs.**

# 5 Glossary of ATV Terms

***Aspect ratio*** — Image width divided by its height. Standard definition analog television uses an aspect ratio of 4:3 and broadcast HDTV uses 16:9.

***ATSC*** — Advanced Television Systems Committee, the group that defined the set of standards and formats for the digital television formats implemented in the Broadcast Television Service. See **DTV**.

***ATV*** — Amateur Television. Sending pictures by Amateur Radio. You'd expect this abbreviation to apply equally to fast-scan television (FSTV), slow-scan television (SSTV) and facsimile (fax), but it's generally applied only to FSTV.

***Back porch*** — The blank part of a scan line immediately following the horizontal sync pulse. See **blanking**.

***Black level*** — The signal level amplitude that corresponds to the black end of the video dynamic range.

***Blanking*** — A "blacker-than-black" signal level that assures that the scanning trace cannot be seen as it is reset to scan another line or frame. In conventional television this is often referred to as the *blanking pedestal*, consisting of two segments — the **front porch** that precedes the vertical sync pulse and the **back porch** that follows the sync pulse.

***Cathode ray tube (CRT)*** — A specialized electron tube, employing a phosphor-coated screen, used for image display. The classic TV "picture tube" used in older television sets and computer monitors, is an example of such a tube.

***Charge-coupled device (CCD)*** — An integrated circuit that uses a combination of analog and digital circuitry to sample and store analog signal voltage levels, passing the voltages through a capacitor string to the circuit output.

***Chrominance*** — The color component of a video signal. NTSC and PAL transmit color images as a black-and-white compatible luminance signal along with a color subcarrier. The subcarrier phase represents the hue and the subcarrier's amplitude is the saturation.

***CODFM*** — Coded Orthoganal Frequency Division Multiplex. A system of a large number of carriers as is used with DVB-T. See **en.wikipedia.org/wiki/CODFM.**

***Color burst*** — Seven cycles of a 3.58 MHz subcarrier signal located on the back porch (see **blanking)** of an NTSC color TV signal waveform. This short burst is locked on to by a PLL in the TV receiver as the reference for the chroma in the video.

***Color subcarrier*** — The modulated 3.58 MHz component of an NTSC color television signal that is used to convey the color or luminance image data.

***Composite video*** — The standard 1 V peak to peak analog video into 75 Ω load signal consisting of color, video, blanking and sync found in consumer products and typically identified with a yellow color coded RCA connector. The sync tip is referenced at 0 V, blanking at 0.285 V, black level at 0.339 V and white at 1.0 V.

***Compression*** — Various digital techniques to reduce the bandwidth, transmission rate or file size of an image.

***Constellation*** — Type of modulation within the specified bandwidth. i.e. QPSK or QAM.

***Deflection*** — the circuits or other components controlling the vertical and horizontal sweep signals that move the scanning beam of a cathode ray tube image display.

***DTV*** — Digital television, most commonly applied to a series of 16 digital formats (including HDTV or High Definition Television) that comprise the default commercial broadcast digital TV standards in the United States.

***DVB-S*** — Digital Video Broadcast - Satellite.

***DVB-T*** — Digital Video Broadcast - Terrestrial.

***FEC*** — Forward Error Correction. A code rate used in DVB-T. 7/8 means 7 data bits for each single FEC bit.

***FFT*** — Fast Fourier Transform is an algorithm used for time and frequency synchronization of the DVB-T carriers. 2K and 8K DVB-T modulator parameter denotes 1705 and 6817 carriers respectively.

***Field*** — Collection of top to bottom scan lines. When interlaced, a field does not contain adjacent scan lines and there is more than one field per frame.

***Frame*** — One complete scanned image. NTSC has 525 lines per frame with about 483 usable after subtracting vertical sync and a few lines at the top containing various information.

***Front porch*** — The blank part of a scan line just before the horizontal sync.

***FSTV*** — Fast-Scan TV. Same as common, full-color, motion commercial broadcast TV.

***Guard Interval*** — The space between symbols or characters and is important for minimizing the effects of multipath. 1/16 means there is one guard space preceding each 16 symbols.

***H.264/MPEG-4*** — A video compression standard used with DTV modulators, recording and video content. See **en.wikipedia.org/wiki/H.264.**

***Interlaced scanning*** — A scanning pattern, designed to reduce perceived flicker in broadcast television systems, in which the complete image frame is actually made up from two sequentially-scanned fields and thus improving the vertical resolution. The timing of the sequential scanning is such that the lines of the second field are interspersed between the lines of the first field. For example, NTSC sends a field with just the even lines in 1/60 second, then a field with just the odd lines in 1/60 second.

***Luminance*** — The brightness component of a video signal and can refer to the white-to-black amplitude or the chroma weighted sum of the gamma-compressed R'G'B' components computed as Y (the luminance signal) = 0.59 G (green) + 0.30 R (red) + 0.11 B (blue).

***MPEG*** — Motion Picture Experts Group, a set of digital image compression formats/standards for moving images.

***MPEG-2*** — A compression format standard for video and audio widely used with DVDs. See **en.wikipedia.org/wiki/MPEG-2.**

***NTSC*** — National Television System Committee. Analog broadcast television standard used in North America and Japan.

***PAL*** — Phase alteration line. Analog television standard used in Germany and many other parts of Europe.

***PID*** — Packet Identifier in a DVB-T data transport stream is similar to CTCSS with FM voice.

***Progressive scanning*** — A scanning sequence in which all image lines are scanned sequentially to display the complete image frame. Used in some **DTV** broadcasts.

***Pixel*** — Picture element, the dots that make up images on a monitor. Image resolution is directly related to the number of picture elements. If the size of a picture element is large relative to total image size, the image will be made up of a relatively small number of picture elements and thus have relatively poor resolution. If the size of a picture element is small relative to total image size, the image will consist of a large number of picture elements and thus demonstrate better resolution.

***Raster*** — The pattern of scanning lines developed on the face of a cathode ray tube during the display of one image frame.

***Resolution*** — The ability to see a number of vertical lines horizontally across the screen. The NTSC analog horizontal scan rate of 15734 Hz limits the luminance resolution to 80 lines per MHz of video response bandwidth. Digital TV's highest resolution is limited by the number of screen pixels. It takes 2 adjacent pixels, one black and one white for one line.

***RGB*** — Red, Green, Blue. One of the models used to represent colors. Due to the characteristics of the human eye, most colors can be simulated by various blends of red, green, and blue light.

***SECAM*** — Sequential color and memory. Analog television standard used in France and the Commonwealth of Independent States.

***Sync*** — That part of a TV signal that indicates the beginning of a frame (vertical sync) or the beginning of a scan line (horizontal sync).

***Vidicon tube*** — A type of photosensitive vacuum tube used in TV cameras.

***White level*** — The white end of the video dynamic range in any image transmission format. The difference between white and black levels defines the video dynamic range of the mode.

***8-VSB*** — 8-level Vestigial Side Band, the standard for broadcast **DTV** in the US.

# 6 Slow-Scan Television (SSTV) Overview

The previous sections discussed fast-scan amateur television, used to send wide-bandwidth full motion video on the 420 MHz and higher frequency bands. In contrast, slow-scan television (SSTV) is a method of sending still images in a narrow bandwidth widely used on the HF bands. SSTV activity can be found on HF, VHF, UHF, repeaters, satellites, VoIP on the Internet, and by almost any means that can transmit and receive a voice signal.

Images are our most powerful communication tool. SSTV allows us to add images to our verbal communications via Amateur Radio. Working with the SSTV mode can provide much more than just swapping pictures. It provides a practical way to learn about radio propagation, computers and computer graphics. As with any activity, the more involved you become, the more knowledgeable you become about all the intricacies.

SSTV is also a great way to get others involved in Amateur Radio or enhance other activities. Consider adding SSTV capability to your emergency communications, public service, Field Day or Jamboree on the Air station. SSTV is a legacy mode that is enjoyed by many hams worldwide. More and more hams are finding this older mode appealing and it is also used by public service teams to support disaster response and recovery efforts.

This section of the *Handbook* is intended to provide an overview of SSTV signals, operation, and equipment configuration. The *SSTV Handbook* by Martin Bruchanov, OK2MNM, is a very thorough resource on all aspects of SSTV and may be downloaded at **www.sstv-handbook.com**.

**Figure 35 — First cross-Atlantic SSTV transmission in 1959.**

## 6.1 SSTV History

SSTV originally involved the transmission of a visual image from a live video source. Images were black-and-white. Specific audio tones represented black, white, and shades of gray, and other audio tones were used for control signals. The receiving station converted the tones back into an image for display on a picture tube. It took 8 seconds to send a picture, and everything fit in the same bandwidth used for SSB transmissions.

Cop Macdonald, WA2BCW, now VY2CM, developed the first SSTV system. Macdonald received the Dayton Hamvention's Technical Excellence Award in 2009 for his SSTV development work. **Figure 35** shows the first SSTV image sent across the Atlantic Ocean to John Plowman, G3AST, by MacDonald in 1959.

For the initial system, MacDonald used a surplus long-persistence phosphor radar monitor to display the images. The images were captured using a vidicon camera or a flying-spot scanner. One frame of video had 120 lines and was sent at a rate of 15 lines per second, requiring 8 seconds per frame. Three frames were sent back-to-back to maintain an image on the monitor. For many years, bulky

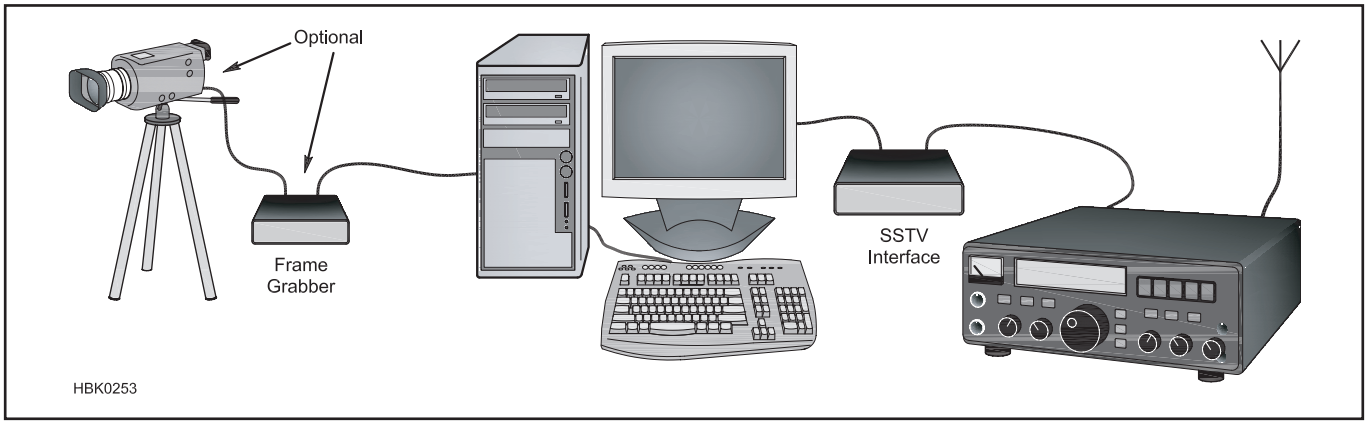

**Figure 36 — SSTV stations need only a sound card equipped PC and simple interface to send and receive SSTV.**

and complex home-built systems were the only way to participate in SSTV.

Robot Research produced SSTV equipment throughout the 1970s and 1980s. The Robot 1200C scan converter, introduced in 1984, represented a giant leap forward for SSTV — all the SSTV functions were performed within a single piece of equipment. A *scan converter* converts signals from one video format to another. In this case, it converted SSTV signals to and from formats intended for fast scan television. This allowed the use of standard video cameras and equipment to capture and display images.

DOS-based PCs became a popular component for SSTV systems in the early 1990s. These hybrid systems were part hardware and part software. Most systems required external equipment to process the audio and perform the analog-to-digital conversion. In 1998, the Tasco Electronics TSC-70 Telereader color scan converter was used on the MIR space station to send pictures from space. Kenwood introduced Visual Communicator VC-H1, a portable SSTV unit that included a built-in camera and LCD monitor. Other scan converters were made, but none are produced today.

The personal computer with a built-in sound card has become the hardware of choice to send and receive images, replacing specialized devices. Today's powerful PCs and SSTV software are the heart of a modern SSTV station. The PC processes the incoming and outgoing SSTV audio using the sound card, while the software manages the acquisition, storage, selection, and editing of the SSTV pictures. With a PC in your ham station, adding software and an interface (to connect the computer sound card to the transceiver) is all that it takes to get started in this fascinating mode. **Figure 36** shows a typical current station SSTV configuration.

# 7 SSTV Basics

Traditional SSTV is an analog mode, but in recent years digital SSTV has been developed. Both make use of standard voice Amateur Radio transceivers — no special radio gear or antennas required. SSTV transmissions occupy only the bandwidth of voice signals and are allowed on any frequency in the HF and higher bands where Image emissions are permitted. These are generally the same band segments used for SSB voice signals.

## 7.1 Computers and Sound Cards

A computer with sound card is required to use most of the software popular for SSTV. Software for the *Windows* operating system is the most popular, but other choices are available. (Software for analog and digital SSTV is discussed later in this section.) Hardware and software setup is similar to that described for sound card modes in the **Digital Communications** chapter of the downloadable supplemental material. The sound card characteristics discussed in the **Digital Communications** chapter apply to SSTV as well. Most sound cards will work, but sample rate accuracy is important for some SSTV modes (more on this later).

Within *Windows*, the MASTER VOLUME and WAVE controls set the levels for the transmitted SSTV audio. All other mixer inputs should be muted. Equalization and special effects should not be used. *Windows* sounds should be disabled to prevent them from being transmitted along with the transmitted SSTV audio. The RECORDING control panel is used to select the input for receiving the SSTV audio. Adjust the LINE IN or MICROPHONE level settings as needed for the proper level. MIC BOOST should not be used.

## 7.2 Transceiver Interface

Interfacing the transceiver to the PC sound card can be as simple as connecting a couple of audio patch cables. Sound cards generally have stereo miniature phone jacks, so use matching plugs when making these connections. Only one audio channel is required or desired — the left channel. This is the tip connection on the plug. Use shielded cable with the shield connected to the sleeve (ground) on the plug. Ground loop problems may be avoided by bonding equipment together or by using an audio isolation transformer. (See the **Digital Communications** chapter for examples of how to connect the transceiver and PC. Another useful resource is the sound card interface web page by Ernie Mills, WM2U, at **www.w0btu.com/wm2u/interface.html**.)

The connection for received SSTV audio from the transceiver may be made anywhere that received audio is available. The best choice is one that provides a fixed or *line level* audio output. This will ensure that recording control levels will not have to be adjusted each time the volume on the transceiver is adjusted. You can use a headphone or speaker output if that's all that is available. If the received output level is enough for the LINE IN input on the sound card, use it, otherwise use the MICROPHONE input. If the level is too high for LINE IN, an attenuator may be required.

Use the LINE OUT connection on the sound card for transmitted SSTV audio. (See the **Digital Communications** chapter's examples for AFSK signals.) If the transceiver does not have a separate input for the audio signal, the microphone input must be used. This requires a more elaborate interface. Transmit-receive (TR) keying can be controlled using the transceiver's VOX. Other methods for activating transmit include manual switching, a serial port circuit, an external VOX circuit, and/or a computer-controlled digital signal output.

Fully-assembled and kit sound card interfaces are available commercially. Most of the sound card interfaces for the digital modes are suitable for SSTV. The microphone will be used regularly between SSTV transmissions, so consider how to conveniently switch back and forth between voice and SSTV operation.

## 7.3 Transceiver Requirements

An SSB voice transceiver with a stable VFO is necessary for SSTV operation. The VFO should be calibrated and adjusted to be within 35 Hz of the dial frequency (more on this later). The transceiver's audio bandwidth should not attenuate the audio spectrum used by SSTV. Filters should be set to 3 kHz or wider. Turn off functions that affect audio bandwidth or linearity, such as transmit or receive audio equalization, noise blanker or noise reduction functions, compression or speech processing, and passband tuning or IF shift.

Adjust the transmitter output for proper operation with the microphone first, according to instructions in your manual. Then connect and adjust the sound card output for the desired audio level. Properly adjusted levels and clean audio quality will improve the reception of the transmitted signal as well as reduce interference on adjacent frequencies.

SSTV transmissions are 100% duty cycle when an image is being sent. If your transceiver is not designed for extended full-power operation, reduce the power output to one-half its maximum output.

SSTV may be transmitted using AM, FM or SSB. Use the same mode as you would use for voice operation on a given frequency. On HF, use the same sideband normally used for voice on that band.

### 7.4 SSTV Operating Practices

Analog SSTV images are, in a sense, broadcast. They are received without error correction or transmission acknowledgement and do not require the recipient to establish a two-way connection. The majority of SSTV operation takes place on 14.230 MHz (more on alternate SSTV frequencies later).

You can establish a contact by voice first before sending the SSTV image, or just ask if the frequency is in use. If the frequency is clear, you can send an SSTV transmission as your CQ. Listen carefully as a station might be sending but you cannot hear them due to propagation. Receiving SSTV images will take place automatically as long as your software supports the mode used for transmission (more on SSTV modes in later sections). Once a picture is received, it will be displayed and may be saved. Some software displays the image as it being received.

When selecting images to send, consider appropriateness, picture quality, and interest to the recipient. Choose an SSTV mode that is suitable for the image to be sent and band conditions. Avoid using ScottieDX or other SSTV modes which require more than 2 minutes of transmission time to avoid occupying the frequency for an excessive period. Sending a CW or voice station ID is not necessary if your call sign is included in the image.

To send a SSTV image, use your software to select and load a picture to send. It will be displayed in a transmit screen. Next, select the SSTV transmission mode. Initiate the transmission and your transceiver will switch to transmit and send the SSTV audio. When the SSTV transmission is over, the transceiver returns to receive. Be sure to send the full frame or the next picture sent may not be received properly if the software does not start scanning from the start of the frame.

#### SOURCE FOR IMAGES

The internet is a popular source for images (pay attention to copyright notices). You can develop and store picture collections by theme, such as airplanes, landmarks, moonlit scenes, or holidays.

A digital camera is one of the best ways to create an original picture of your own. The subject matter could be almost anything that you might have available. Pictures of the shack, equipment, and operator are always welcomed. A live camera or web cam can provide a quick snapshot. For those who like to discuss technical details, diagrams and schematics might be your chosen subject. A flatbed scanner is ideal for importing diagrams, schematics, and photographs. Screen shots of what is on the computer monitor can be saved simply by using the PRINT SCREEN or PRTSCRN key. Use the Paste function in *Windows* to transfer the image to your SSTV or image editing software.

Include your own personal drawings. Make your images colorful with lots of contrast to make them really stand out. You can also transmit pictures of your home, areas of local interest, other hobbies, projects, maps, cartoons, and funny pictures.

Any image editing program can be used to make your own CQ image, test pattern, video QSL card, or "73" picture. Use the JPG or BMP image format and crop images to 320 × 256 pixels.

It is common to have call sign, location, and perhaps a short description as text on the pictures. If two call signs are placed on an image, it is understood that the sender's call sign is placed last. Signal reports may also be included. This information is not typically embedded in the image. Instead, the SSTV software has a text editor to overlay this variable data on to the selected picture before each transmission.

# 8 Analog SSTV

SSTV is a video mode that uses analog frequency modulation. Every different brightness level in the image corresponds to a different audio frequency. The modulating frequency ranges from 1500 to 2300 Hz, corresponding to the brightness of the video component. The frequency of video signal varies from black by shades of gray to white. The amplitude of the signal does not affect the brightness, only the signal-to-noise ratio (SNR) of the signal. Color is achieved by sending the brightness of each RGB color component separately. The original image is scanned from left to right, in green, blue and red order for Martin and Scottie modes.

Although SSTV is an image signal mode, the format of the signal by which brightness and color are encoded is also called a mode. The various modes have different resolutions and scan rates.

**Table 2** contains a summary of SSTV ana-

**Table 2**
**Analog SSTV Modes**

| *Family* | *Developer* | *Name* | *Color* | *Time* | *Lines* |
|---|---|---|---|---|---|
| AVT | Ben Blish-Williams, AA7AS / AEA | 8 | BW or 1 of R, G, or B | 8 s | 128×128 |
| | | 16w | BW or 1 of R, G, or B | 16 s | 256×128 |
| | | 16h | BW or 1 of R, G, or B | 16 s | 128×256 |
| | | 32 | BW or 1 of R, G, or B | 32 s | 256×256 |
| | | 24 | RGB | 24 s | 128×128 |

log modes for both black and white (B&W) and color. Color SSTV images are the standard today. (See the chapter "Formats of slow-scan TV transmission" in OK2MNM's *SSTV Handbook* in the references listings for a complete description of SSTV image signals.)

## 8.1 Color SSTV Modes

Two popular modes for sending and receiving color SSTV pictures are called Martin and Scottie (named after their developers — see Table 2). During a three-day study in 2014, 89 percent of the images received worldwide at WB9KMW were from these two modes. Within each family are several different varieties, for example Martin 1, Martin 2, Scottie 1, and Scottie 2.

Information about the size or resolution for each mode is generally available in the SSTV software. Slower scan rates can provide better quality; those are the modes that take longer to send for the same resolution.

For example, Scottie 1 and Martin 1 are popular RGB (red, green, blue) color modes that take about two minutes to send a frame. The image size sent is 320 × 256 — 320 pixels across with 256 lines. See **Figures 37** and **38**. True color is possible since each pixel is sent with 256 possible levels for each of the three different color components, red, green and blue.

Each mode has a *vertical interval signaling* (VIS) code that identifies the mode being sent. The code is sent during the time between frames, called the *vertical interval*. The VIS codes use 1100 Hz for 1, 1300 Hz for 0, and 1200 Hz for start and stop. When a VIS code is received, receiving system configures itself for the proper SSTV mode.

For VIS code detection to work, the receiver must be tuned within 70 Hz of the transmitted frequency. Two stations tuned exactly on the SSTV frequency but with VFO errors of +35 Hz and –35 Hz could successfully pass the VIS codes. As mentioned previously, each transceiver must have the VFO and display calibrated within 35 Hz to ensure VIS code detection with the transceiver set to the SSTV frequency. Using the sync pulse rate is another way to determine the mode when the VIS is not decoded. If a station sending is far off frequency, use the 1200 Hz sync signal in the spectrum or waterfall as a guide to adjust the VFO.

Received images are displayed in near real time as they are decoded. Almost any SSTV signal that is heard can produce an image, but it is rare to receive an image that is perfect. Changes in propagation, noise, and other interferences will become apparent as the image continues to scan down the screen. Noise will damage the lines received just as it occurs. Interference from other signals will distort the image or perhaps cause reception to stop. Signal fading may cause the image to appear grainy. Multipath will distort the vertical edges. Selective fading may cause patches of noise or loss of certain colors.

Images that are received with staggered edges are the result of an interruption of the sound card timing. Check with other operators to see if they also received the image with staggered edges. If not, then it may be your computer that has the problem and not the sending station. Some possible solutions are to close other programs, disable antivirus software and reboot the computer.

## 8.2 Communicating in Color

While an image transmitted from the home station may appear very attractive at the sending station, it can be very difficult or impossible to view on the receiving end. Signals often deteriorate significantly due to propagation, noise and other factors. The operator can take steps to maximize the received image quality. The two most important factors are font size for characters and color contrast.

First, choose a large text font so the text can be read even in the presence of noise. Then for high visibility and readability of text in the image, high contrast is crucial. Problems arise from the choice of pastels and less than distinct color combinations. The top four most visible color combinations are black text on a yellow background, black over white, yellow over black and white over black.

When attempting to communicate effectively via SSTV, do the following:

- Keep it simple. Keep the wording short and succinct.
- Keep it big. Large text allows hams to view your message clearly.

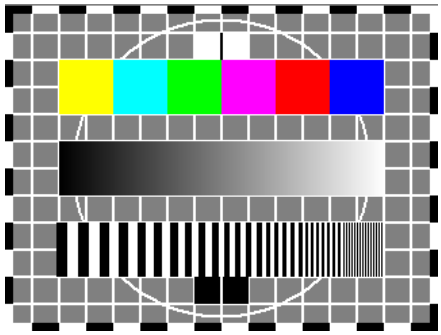

**Figure 37 — This color test pattern is 320 × 256 resolution. The Robot modes from the 1980s only used 240 lines. CRTs were 4:3 aspect ratio, so the images were displayed in 320 × 240 resolution. When Scottie 1 and Martin 1 modes were added, they kept this resolution but added 16 header lines to the top to aid in synchronization. These 16 header lines, shown as the solid gray area at the top, are now used as part of the image and include the sender's call sign and other information.**

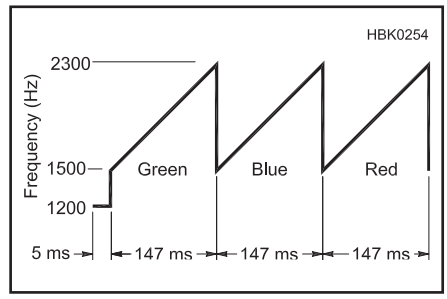

**Figure 38 — This is a diagram of a single scan line of a Martin 1 transmission. The full frame includes 256 horizontal scan lines starting at the top. Before each line, a 1200 Hz tone for 5 ms is sent for synchronization. The pixels are scanned left to right and the colors are sent sequentially. First the green component is sent for each of the 320 pixels of one scan line — 256 values are possible from black to pure green. Next, is the blue component, and the red component is sent last (again, 256 possible values for each color). It takes 147 milliseconds to send each of the three color components. The result is 114 seconds to send the complete frame.**

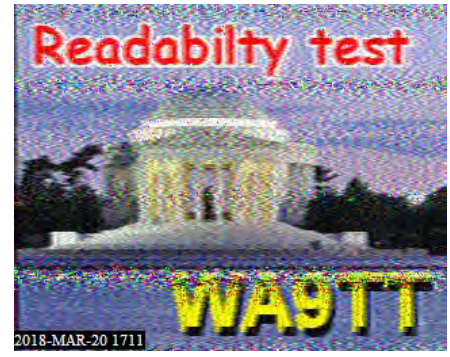

**Figure 39 —Text is easiest to read when properly sized and contrasts well with the image background.**

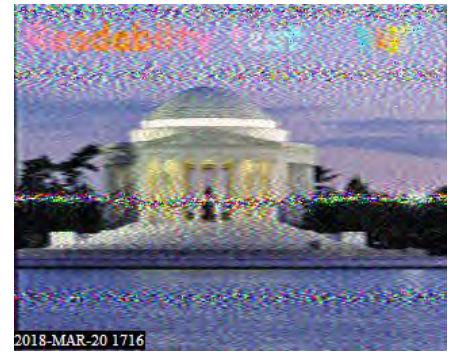

**Figure 40 —This image is harder to read due to poor choice of font size and color contrast in the presence of noise artifacts in the received image.**

• Keep it clean. Avoid using thin fonts, as well as most script fonts. Use thick, heavy fonts to maximize readability.

• Keep it colorful. High color contrast is the key ingredient.

**Figures 39 and 40** illustrate how readability is affected by font size and color contrast, as copied by a distant station. Both images carry the same text message.

## 8.3 SSTV Signal Reporting

Traditionally, hams have used an RSV system to give an SSTV signal report. This parallels the RST report given on CW and RS for SSB contacts. RSV denotes:

• **R**eadability for the template words
• **S**trength of the transmission
• **V**ideo quality

R = 5 is perfectly readable text. S = 9 denotes an extremely strong signal. V = 5 means the video is crystal clear without any blemishes. Although 595, 575, and the occasional 555 report are given, a true V = 5 image is fairly rare. Thus, the traditional RSV signal reporting system does not provide a lot of information to the transmitting station operator.

An alternative SSTV reporting P-quality system is gaining in popularity similar to the reporting system for fast-scan ATV. There are six levels from P5 to P0. These levels are based on image research that assigned data quality rating compared to an original image.

• P5: 100% to 97.7% received, broadcast quality with minimal distortion. See **Figure 41**.

• P4: 97.7% to 84.1% received, a good image with a few noise lines. See **Figure 42**.

• P3: 84.1% to 50% received, the most common image quality on 20 meters. These pictures are usable but noisy. See **Figure 43**.

• P2: 50% to 15.9% received, the SSTV signal is not strong enough to overcome the noise. These images are quite noisy and barely usable. See **Figure 44**.

• P1: 15.9% to 2.3% received, images during poor signal reception. One can barely see the text and the picture is far from distinct. See **Figure 45**.

• P0: 2.3% to 0% received, images are totally unusable. See **Figure 46**.

## 8.4 SSTV Cams

A few hams around the world routinely monitor SSTV transmissions, typically on 14.230 MHz, and then immediately post that information on their website servers for display on web pages. These sites are referred to as "SSTV cams." Similar to the Reverse Beacon Net (RBN), PSKReporter, and WSPRNet systems, some stations go further by collecting SSTV cam images and aggregating those images onto one web page for viewing.

This information is helpful in two ways:

Figure 41 — P5: Broadcast quality

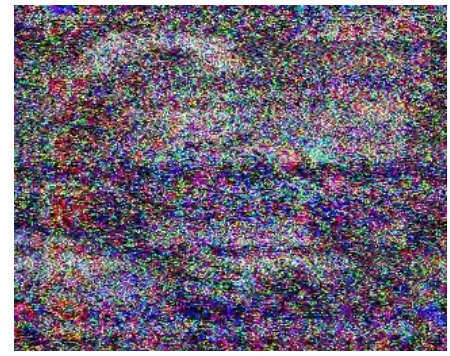

Figure 42 — P4: Good, some noise

Figure 43 — P3: Usable, but noisy.

Figure 44 — P2: Barely usable, noisy.

Figure 45 — P1: Text is barely visible.

Figure 46 — P0: Unusable

1) Propagation. You can view how well your transmission was received by a variety of stations by looking at those SSTV cams. You can immediately assess 20 meter band conditions. You will know which areas are receiving your transmission and where you have no reception.

2) Station relay. When you are in the midst of an SSTV QSO, all sorts of things happen, such as QSB, QRM, and QRN. All interfere with your ability to receive the latest transmission. By using these SSTV cams as "relay stations" to supplement your station's reception, you will be able to enjoy a richer QSO.

There are a few major websites around the world which offer a variety of SSTV cams for your viewing, such as:

• CQSSTV at **cqsstv.com**
• GØHWC at **g0hwc.com**
• WA9TT at **wa9tt.com**
• World SSTV Cams at **worldsstv.com**

## 8.5 SSTV Operating Frequencies

SSTV operation centers on several frequencies in the HF and VHF range. Use the customary phone sideband for the band being used. Most contacts occur on 20 meters on 14.230 MHz for analog SSTV and on 14.233 MHz for digital SSTV. (Move 3 kHz above or below these frequencies to have an extended contact if the band is busy.) **Table 3** lists a number of popular frequencies used in North

**Table 3**
**SSTV Frequencies**

**Analog**

| *Band (Meters)* | *Frequency (MHz)* | *Modulation* |
|---|---|---|
| 160 | 1.890 | LSB |
| 80 | 3.845, 3.730 in Europe | LSB |
| 40 | 7.171, 7.040 in Europe | LSB |
| 20 | 14.230 | USB |
| 17 | 18.117 | USB, N-SSTV (see text) |
| 15 | 21.340 | USB |
| 12 | 24.927 | USB, N-SSTV (see text) |
| | 24.975 | USB, All modes |
| 10 | 28.680 | USB |
| 2 | 145.500 | FM |
| ISS SSTV Downlink | 145.800 | FM |

**Digital**

| *Band (Meters)* | *Frequency (MHz)* | *Modulation* |
|---|---|---|
| 80 | 3.843, 3.733 in Europe | LSB |
| 40 | 7.173 | LSB |
| 20 | 14.233 | USB |
| 15 | 21.343 | USB |

America and Europe. Remember that these frequencies are not dedicated to SSTV and may be occupied with other signals. Having a backup frequency or using another band to avoid congestion is good practice.

In the late afternoon and evening hours, regional activity switches to 40 and 75 meters, with some contacts on 160 meters. In the United States, 7.171 MHz and 3.845 MHz are commonly used, although 7.171 MHz is only available to Extra Class licensees.

Locally, a 2 meter SSTV net may be active either on the SSTV calling frequency of 145.500 MHz or perhaps on an FM repeater. (Before using a repeater for SSTV contacts, be sure the repeater owner approves.)

Occasionally the International Space Station will broadcast SSTV pictures on 145.800 MHz. Check **ariss-sstv.blogspot.com** for the operating schedule. A simple antenna and a common FM transceiver can be used for reception as shown in **Figure 47**. ISS passes visible at your location can be determined by a satellite tracking program or via a website such as **heavens-above.com**.

**Figure 47 — Image received from the International Space Station.**

## 8.6 Narrow SSTV

Due to crowded conditions on 20 meter SSTV, "Narrow SSTV" or N-SSTV has become popular. This is an analog SSTV transmission with an audio signal only 500 Hz wide, extending from 1900 to 2300 Hz. Contrast that with normal SSTV, which has a VIS marker at 1200 Hz and image intensity is transmitted between 1500 and 2300 Hz.

It is useful to enable your software to use the FSKID method of call sign identification during the transmission. The PLL demodulation technique seems to work best for receiving N-SSTV pictures.

N-SSTV is acceptable on the usual SSTV operating frequencies and on 17 meters. It may be used on the 12 meter band as long as you follow the requirements of FCC Part 97.307(f):

*(1) No angle-modulated emission may have a modulation index greater than 1 at the highest modulation frequency.*

*(2) No non-phone emission shall exceed the bandwidth of a communications quality phone emission of the same modulation type.*

There has been some discussion of using N-SSTV on the 30 meter band. The ARRL's understanding of the FCC rules is that image transmissions of any type are not permitted on 30 meters, regardless of whether the transmission encoding is digital or analog. For that reason, the ARRL does not include 30 meters in Table 3.

## 8.7 Software for Analog SSTV

A variety of software programs are available for SSTV (see **Table 4)**. Some multimode programs include SSTV and digital modes, while others are dedicated to SSTV. One very popular SSTV package is the *Windows* program *MMSSTV* by Mako Mori, JE3HHT. For more information or to download a copy, visit **hamsoft.ca/pages/mmsstv.php**. *MMSSTV* will run on an old 100 MHz PC, but some features may require a faster processor. Other SSTV software has similar features.

As explained in the **Digital Communications** chapter, sound card sample rate accuracy is important for some modes. Analog SSTV is one of them: pictures will appear *slanted* if the clock is off. (See **Figure 48**.)

The *MMSSTV* Help file includes detailed information on several ways to do a quick and easy calibration (see the Slant Corrections section). The best method is the one that uses a time standard such as WWV. (Before performing this calibration procedure, you must have the sound card interface connected so *MMSSTV* can detect received audio.) After performing the clock calibration, chances

are, the timing will also be correct for transmit. If not, *MMSSTV* provides a means for making a separate adjustment for transmit. Alternatively, two alternative approaches for adjusting receive and transmit slant are discussed in depth in tutorials at **wa9tt.com** titled "That Pesky Slant." Help for analog SSTV is available on Yahoo Groups MM-SSTV: **groups.yahoo.com/groups/MM-SSTV.**

**(A)** **(B)**

**Figure 48 — If the sound card clock is inaccurate, analog SSTV images may appear slanted (A). The same image is shown at B after calibrating the clock.**

# 9 Digital SSTV

Several forms of digital SSTV (DSSTV) have been developed, but the modulation method most widely used for digital SSTV is derived from the shortwave broadcast system Digital Radio Mondiale (DRM). (Mondiale is a French word meaning "worldwide.") Like analog SSTV, a majority of activity occurs on 20 meters, specifically on 14.233 MHz. (See Table 3.)

HamDRM by Francesco Lanza, HB9TLK, is a variation of DRM that occupies a 2.5 kHz bandwidth and is used in various programs. The signal occupies from 350 to 2750 Hz (see **Figure 49**). As many as 57 subcarriers may be transmitted simultaneously, all at the same level. Three pilot carriers are sent at twice the level as the others. The subcarriers are modulated using *coded orthogonal frequency division multiplexing* (*COFDM*) and *quadrature amplitude modulation* (*QAM*). Each *main service channel* (*MSC*) frame or segment has a duration of 400 ms and several methods of error correction are used within the segments. (See the **Modulation** chapter for more information on ODFM and QAM.)

HamDRM is not a weak-signal mode like the narrow bandwidth data modes such as PSK31. An S-9 or better signal with little or no noise may be required before the software is able to achieve a sync lock. MSC sync lock is required before any data can be decoded and displayed.

The quality of a DSSTV signal far exceeds that of analog SSTV. Distortion-free images are exact reproductions of the original transmission. However, there are drawbacks:

1) Band conditions. They must be favorable for reception and clear of most QRM and no significant QSB. Strong signals ensure quality reception.

2) Sufficient data segments must be received. When an insufficient number of segments are received, the software will simply fail to decode and no image will be seen. Contrast that to analog SSTV where a weak image, perhaps P2 quality, can still be displayed even with strong noise or interference. Transmit encoding may be changed to send duplicate or redundant segments. Normally a setting of RS1 or RS2 is used. When band conditions aren't good, a higher setting of RS3 or RS4 may be used, however, this increases the transmission time. A receiving station may request re-transmission of missing segments via a BSR, or Bad Segment Request. The receiving station transmits the BSR indicating the missing segments to be retransmitted for a "fill" of the picture.

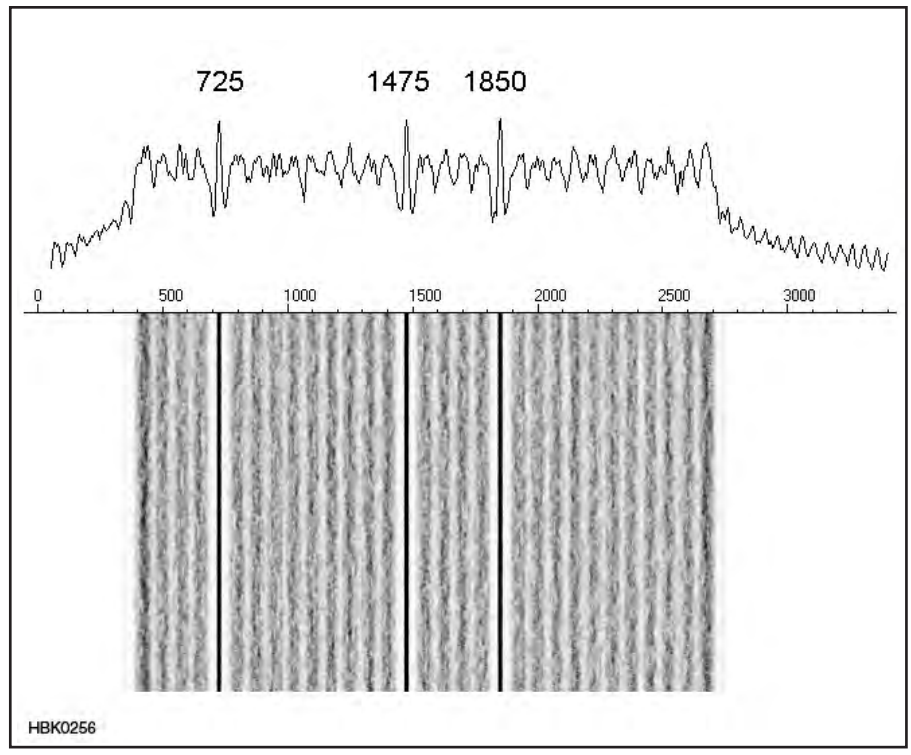

**Figure 49 — HamDRM signal spectrum above and waterfall below. Transmissions may have slightly different characteristics due to the many possible submodes. HamDRM transmissions have three pilot carriers with an amplitude twice that of the remaining subcarriers. These pilot carriers are found at 725, 1475 and 1850 Hz and aid in adjusting the frequency of the receiver to match the transmitted signal. Software can compensate for mistuning by as much as ±100 Hz, but only if the offset is stable (little or no drift in frequency). The overall response should be flat, producing a level amplitude across the full spectrum provided that the signal is not affected by propagation. The waterfall should show the same intensity across the full signal. The bandwidth can be as much as 2.4 kHz, starting at 350 Hz and ending about 2750 Hz. Some roll-off can be tolerated.**

## 9.1 Digital SSTV Setup

A popular digital SSTV program is *EasyPal* by the late Erik Sundstrup, VK4AES. Digital SSTV uses the same type of PC and sound card setup as for analog SSTV, but a more capable computer is required. For *EasyPal*, a 2 GHz or faster PC running *Windows XP* or newer operating system is required. As soon as the *EasyPal* software is installed, it is ready to receive pictures.

Unlike analog SSTV, the software detects and compensates automatically for clock timing differences so sound card calibration is not required. The software also adjusts for ±100 Hz mistuning.

HamDRM sends the transmitting station's call sign continuously. This may allow others to identify the transmitting station and optimize reception. Many submodes are available, with various transmission speeds and levels of robustness. The submodes are automatically detected and receiving starts automatically. Decoding is done on the fly, so there is no waiting for the computer to finish processing before the image appears.

Power output may appear low as measured by a conventional wattmeter. The actual signal strength as seen by others should be about the same as the SSB voice signal. Do not use dc-blocking capacitors in the audio lines as they may change the phase of the received carriers which disrupts the decoding process.

Audio levels from the sound card to the transceiver are low when using HamDRM and may not trigger a VOX circuit reliably at normal settings. Set the transceiver for full RF output. Then adjust the sound card VOLUME CONTROL output until the transmitter shows little or no ALC indication. With an FM transmitter, keep the output level low to avoid overdeviation. Adjust the VOX GAIN sensitivity for reliable operation.

## 9.2 Operating Digital SSTV

If you have not operated SSTV before, try analog SSTV before digital. Copy some images to make sure the sound card setup is correct. The level adjustments for analog SSTV are not as critical as those for DRM. Once you have everything set correctly for analog SSTV, it will be easier to make adjustments for digital SSTV.

When using digital SSTV, if a sending station is far off frequency, use the pilot carriers

as seen in the software spectrum display as a guide. (See Table 3 for digital SSTV frequencies.) Adjusting the VFO while receiving an image is not advised as it will delay synchronization.

The signal-to-noise ratio (SNR) displayed in the software is a measure of the received signal quality. The higher the SNR the better — decoding will be more reliable. Because of the way the software measures the SNR, the peak value displayed for SNR may require 20 to 30 seconds of reception. Adjustments made on either end may change the SNR.

Under very good band conditions the SNR may exceed 18 dB. In that case, a higher speed mode may work. Sub-modes with less data per segment take longer to send, but they are more robust and allow for solid copy even if the SNR is low.

## GETTING THE WHOLE PICTURE

Noise and fading may prevent 100% copy of all the segments. Any missing segments may be filled in later. Your software can send a *bad segment report (BSR)* that lists all the missing segments for a file that has been partially received. In response, the other station can send a *FIX* (resend bad segment request) which should complete the file transfer. If not, the BSR and FIX process may be repeated.

Digital SSTV is very interactive and may involve several stations on frequency sharing images. FIX transmissions intended for another station may provide some of your missing segments — or even all of them. A third party that copied the original transmission may also send a FIX segment or resend the image. Incremental file repair is possible even after several other transmissions are received. The more stations on frequency, the better the chance that one of them is in a position to help out with a FIX.

*EasyPal* has a feature to provide a higher level of error correction so that 100% copy of all the segments is not necessary to receive the complete file. The transmitted file is encoded with redundant data so that the original file may be recreated even though not all the segments were received. The receiving station must also be running *EasyPal*.

Encoded files have interleaved redundancy using Reed-Solomon (RS) error correction. (See the **Digital Protocols and Modes** chapter for more information about error detection and correction.) Four different levels of RS encoding may be selected before the file is sent.

Very Light Encode (RS1) is the lowest level. Transmission time for a file using RS1 will be increased by 13%. When receiving a file encoded with RS1, only 90% of the segments must be received before the file can be decoded and a picture displayed. This may happen even before the transmission is complete. Receiving RS encoded files is automatic; there is no need to select it for receive. Decoding of the file received with RS encoding will occur automatically. The use of RS encoding on the HF bands can reduce the need for BSRs and FIXs and has been found to make the file transfer process more efficient. Encoding may not be necessary on noise-free channels such as VHF FM.

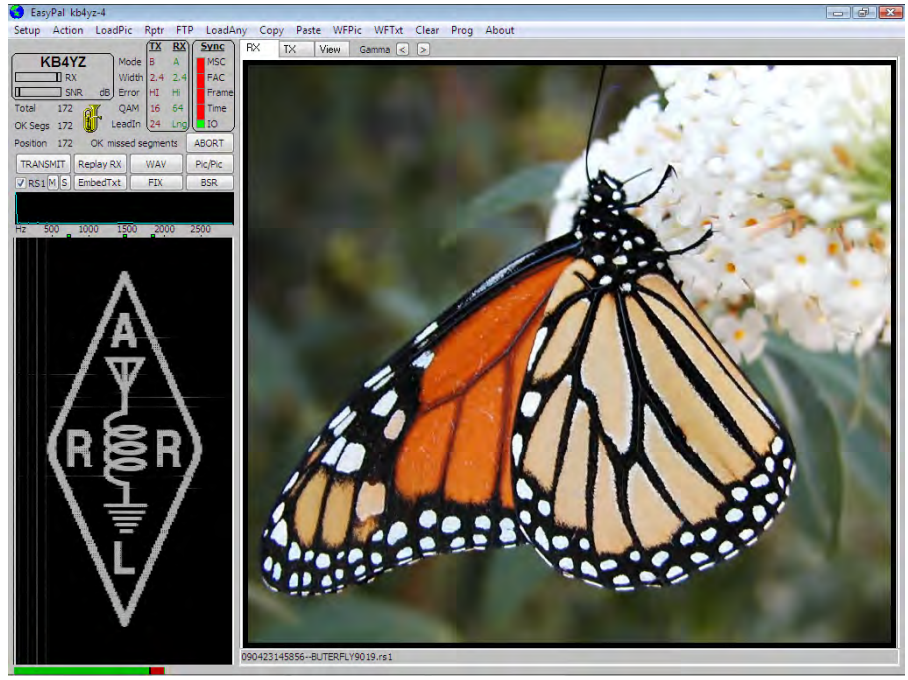

**Figure 50 — *EasyPal* digital SSTV software is used to exchange high quality, color images. Several levels of error correction and various transmission speeds are available.**

Propagation only becomes a factor as it may take longer for the data to get through during poor conditions. The images received will be identical to the ones sent because the data in the files will also be identical. Replays will always be an exact copy. Multipath propagation does not disrupt DRM transmissions unless it is severe or results in selective fading.

**Figure 50** shows an *EasyPal* screen following successful reception of an image.

## IMAGE SIZE

Pictures of any size or resolution may be sent over digital SSTV. The sending station must pay careful attention to file size, though, or the transmission time may become excessively long. Compressing image files is necessary to get the transmit time down to a reasonable amount. Most images will be converted into JPEG 2000 (JP2), a lossy compression method that shows fewer artifacts. A slider varies the JP2 compression level, and a compromise must be made between image quality and file size. The smaller the file, the more visible the artifacts, but the faster it is sent.

Small image files may be sent without using compression. Some file types such as animated GIF files cannot be compressed, so they must be sent "as is."

A "busy picture" is one that shows lots of detail across most of the image area. This type of picture can be challenging to compress into a file size small enough to send that still maintains acceptable quality. Reducing the resolution by resizing and creating a much smaller image is the solution. Just about any busy picture can be resized down to 320 × 240 pixels, converted into JP2, and still look good when displayed on the receiving end.

About 2 minutes of transmission time is the acceptable limit for the patience of most SSTV operators. A typical HamDRM digital SSTV transmission will take about 105 seconds for a file 23 kB in size, RS1 encoded, and requiring 209 segments.

## SENDING DIGITAL SSTV IMAGES

The ideal HamDRM signal will have carriers extending across the 350 to 2750 Hz spectrum. The transceiver should be allowed to pass all frequencies within this bandwidth. In order to maintain the proper phase relationships between all the subcarriers, the signal must be amplified linearly. Avoid overdriving the transmitter and keep the ALC inactive or at the low end of its range. Eliminate hum and other stray signals in the audio.

The process of transmitting an image starts with selecting an image and resizing or compressing it if needed, as described in the previous section. Within *EasyPal*, when the transmit button is clicked, the image file will be RS encoded if that option is selected. Then the resulting file will be broken down into segments and sent using HamDRM.

In receiving HamDRM, the audio is decoded and segments that pass the error check will have their data stored in memory. When enough of the segments are successfully received, the RS file is decoded and the JPEG 2000 image file is created. The content of this file should be identical to the JPEG 2000 image file transmitted.

It can be quite gratifying to receive your first digital SSTV picture. A lot has to go just right, and there is little room for error. Propagation and interference can disrupt the signal. There is no substitute for a low-noise location and good antenna when it comes to extracting the image. Help for all aspects of digital SSTV is available on Yahoo Groups DIGSSTV at **groups.yahoo.com/groups/digsstv**. Be patient and when the right signal comes by you will see the all the lights turn green and the segment counter will keep climbing resulting in an excellent picture!

# 10 Glossary of SSTV Terms

### ANALOG SSTV TERMS

***AVT*** — Amiga Video Transceiver. 1) Interface and software for use with an Amiga computer; 2) a family of transmission modes first introduced with the AVT product.

***Back porch*** — The blank part of a scan line immediately following the horizontal sync pulse.

***Chrominance*** — The color component of a video signal. Robot color modes transmit pixel values as luminance (Y) and chrominance (R-Y [red minus luminance] and B-Y [blue minus luminance]) rather than RGB (red, green, blue).

***Demodulator*** — For SSTV, a device that extracts image and sync information from an audio signal.

***Field*** — Collection of top-to-bottom scan lines. When interlaced, a field does not contain adjacent scan lines and there is more than one field per frame.

***Frame*** — One complete scanned image. The Robot 36-second color mode has 240 lines per frame

***Frame Sequential*** — A method of color SSTV transmission that sent complete, sequential frames of red, then green and blue. Now obsolete.

***Front porch*** — The blank part of a scan line just before the horizontal sync.

***Header***—The information preceding the main signal that holds information about the picture. This is essential to successful reception.

***Interface***—The electronic equipment that connects, or interfaces, your computer to the transceiver.

***Interlace*** — Scan line ordering other than the usual sequential top to bottom. AVT "QRM" mode is the only SSTV mode that uses interlacing.

***Line Sequential*** — A method of color SSTV transmission that sends red, green and blue information for each sequential scan line. This approach allows full-color images to be viewed during reception.

***Luminance*** — The brightness component of a video signal. Usually computed as Y (the luminance signal) = 0.59 G (green) + 0.30 R (red) + 0.11 B (blue).

***Martin*** — A family of amateur SSTV transmission modes developed by Martin Emmerson, G3OQD, in England.

***Pixel*** — Picture element. The dots that make up images on a computer's monitor.

***P7 monitor*** — SSTV display using a CRT having a very-long-persistence phosphor.

***RGB*** — Red, Green, Blue. One of the models used to represent colors. Due to the characteristics of the human eye, most colors can be simulated by various blends of red, green, and blue light.

***Robot*** — (1) Abbreviation for Robot 1200C scan converter; (2) a family of SSTV transmission modes introduced with the 1200C.

***Scan converter*** — A device that converts one TV image format to another. For example, the Robot 1200C converts SSTV to and from FSTV.

***Scottie*** — A family of amateur SSTV transmission modes developed by Eddie Murphy, GM3SBC, in Scotland.

***SNR***—Signal-to-Noise Ratio. The higher the SNR, the clearer the received signal.

***SSTV*** — Slow Scan Television. Sending still images by means of audio tones using transmission times of a few seconds to a few minutes.

***Sync*** — That part of a TV signal that indicates the beginning of a frame (vertical sync) or the beginning of a scan line (horizontal sync).

***VIS*** — Vertical Interval Signaling. Digital encoding of the transmission mode in the vertical sync portion of an SSTV image. This allows the receiver of a picture to automatically select the proper mode. This was introduced as part of the Robot modes and is now used by all SSTV software designers.

***Waterfall***—This is a representation of the received (or transmitted) signal. It is displayed as a moving image that scrolls downward in the SSTV software as time progresses.

***Wraase*** — A family of amateur SSTV transmission modes first introduced with the Wraase SC-1 scan converter developed by Volker Wraase, DL2RZ, of Wraase Electronik, Germany.

### DIGITAL SSTV TERMS

***Bad segment report (BSR)*** — A BSR is sent by the receiving station when an image is not received completely. Once the BSR is received a FIX screen is shown allowing the transmitting station to select the picture to fix or simply fix the last image sent. Only bad segments will be resent.

***COFDM*** — Coded Orthogonal Frequency Division Multiplex, a method of using spaced subcarriers that are phased in such a way as to reduce the interference between them, plus coding to provide error correction and noise immunity.

***Constellation*** — A set of points in the complex plane that represent the various combinations of phase and amplitude in a QAM or other complex modulation scheme.

***Cyclic redundancy check (CRC)*** —A mathematical operation. The result of the CRC is sent with a transmission block. The receiving station uses the received CRC to check transmitted data integrity to determine if the data received is good or bad.

***Digital Radio Mondiale (DRM)*** —A system for digital sound broadcasting in bands between 100 kHz and 30 MHz developed by a consortium of broadcasters, manufacturers, research and governmental organizations. Amateurs use a modified version (HamDRM) for sending digital voice and images.

***Error Protection*** — DRM submode selection. The HI level provides a greater amount of **FEC** used within the segment.

***Fast access channel (FAC)*** — Auxiliary channel always modulated in 4QAM. Contains the submode and station information.

***FEC*** — Forward error correction, an error-control technique in which the transmitted data is sufficiently redundant to permit the receiving station to correct some errors.

***FIX*** — A response to a received BSR. You have the option to FIX an incomplete image that has been received by another station.

***LeadIn*** — The number of redundant segments sent at the beginning of the DRM file transmission to allow the receiving station to become synchronized.

***Main service channel (MSC)*** — Contains the data. Can be modulated in 4QAM, 16QAM or 64QAM.

***Mode*** — In digital SSTV, a particular submode of a DRM transmission. The amount of data in each segment is determined by the submode selected. Robustness varies for each submode.

***QAM*** — Quadrature Amplitude Modulation. A method of simultaneous phase and amplitude modulation. The number that precedes it, for example 64QAM, indicates the number of discrete stages in each pulse.

***Reed-Solomon error correction*** — A data encoding process that inserts redundant data so that errors in reading the data may be detected and corrected. *EasyPal* software provides four levels ranging from Very Light Encode (RS1) to Heavy Encode (RS4).

***Resolution***—The resolution of an image is the detail of that picture. Higher resolutions result in large image sizes and therefore take longer to transmit but will result in a received image having greater detail.

***RS Files***—These are encoded files using the Reed Solomon encode/decode protocol.

***Segment*** — A portion of the transmitted image. Many segments make up the total image. Bad segments can be re-sent faster than resending the total image. It contains file name or transport ID and data.

***Thumbnail***—This is a miniature view of an image.

***TUNE*** — In DRM, a three-tone transmission used to set levels, check for IMD and adjust frequency.

# Station Accessories and Projects

An Amateur Radio station is much more than the transceiver, amplifier and other major pieces of equipment found in a typical ham shack. In this chapter you will find a number of accessory items to make operation more convenient, or to tie other pieces of equipment together. Projects include antenna matching and switching solutions, transceiver/computer interfaces and other station accessories. Additional station accessory projects may be found with the downloadable supplemental content.

## 1 A 100-W Compact Z-Match Antenna Tuner

A Z-Match tuner will match just about anything on all HF bands, and only uses two controls. They are well regarded, but acquiring the necessary air-wound inductors and variable capacitors can be difficult. In addition, air-wound inductors imply large tuners. The antenna tuner described here by Phil Salas, AD5X, is compact enough for portable HF operation, handles 100 W and uses readily available parts. The Z-Match circuit was originally described in "Multiband Tuning Circuits" by R.W. Johnson, W6MUR, in July 1954 *QST* and the article is included in this book's supplemental material.

The idea for this project came from an article by Charles Lofgren, W6JJZ, in the *ARRL Antenna Compendium Vol 5*. In that article, the author suggested using a toroid core-based inductor. This would solve the air-core inductor/size problem. Suitable variable capacitors are available at a good price. The result is the compact unit shown in **Figure 1**.

**Figure 1 — The Z-Match Tuner handles 100 W and can be used from 80 through 10 meters.**

### TUNER CONSTRUCTION

The final circuit shown in **Figure 2** is based on W6JJZ's article. The only real change was to go from two switch-selected output links (10 turns and 4 turns) to a single 8-turn output link, and to increase the variable capacitor size to 400-pF. The tuner provides a good match from 80-10 meters!

The tuner is built into a 3 × 5¼ × 5⅞ inch (HWD) aluminum box. Toroid T1 is supported by its leads and some hot glue between the inductor and the frame of C2. Also put a little hot glue between T1 and the side of the case.

The variable capacitors must be insulated from ground, therefore mount both capacitors on a piece of single-sided circuit- or perf-board that is cut just wide enough to fit into the aluminum case. Then mount this capacitor/perf-board assembly in the case with stand-off screws. Capacitor shaft couplings are made from a ⅛-NPT brass nipple, available from the plumbing section of most hardware stores. These nipples have a ¼-inch inside diameter. Cut a 1-inch nipple in half to make two couplers. Then drill and tap holes for two #6 screws in each piece. See **Figure 3** for capacitor mounting and shaft coupler details. For the insulated shafts, use ¼-inch diameter nylon rods available from many hardware stores.

## OPERATION

Tuning the Z-Match tuner is very easy. First adjust C2 for maximum receiver noise. Then apply some RF power and adjust C1 and C2 for minimum SWR. If you need more capacitance for matching, use S1 to switch in the extra section of C1, or switch in a fixed mica capacitor across C1. Balanced feed lines terminated in banana plugs can plug right into the center pin of the output SO-239 and the adjacent banana jack. To feed coax, ground one end of the output link with switch S2.

## OPTICAL HF SWR METER FOR THE Z-MATCH TUNER

While you can use any external SWR meter with the Z-Match tuner — including the SWR meter built into most rigs — the author built an optical SWR meter into the same case for convenience. Refer to **Figure 4A**. It works well with high intensity LEDs rather than conventional meters. The SWR meter is built on a small piece of perf-board and mounted to the solder lug on the tuner's input SO-239. A little hot glue between the perf-board and the back of the chassis adds stability (**Figure 5**).

This broadband circuit works well at the 100-W power level through at least 30 MHz. With careful lead control, it should work up through 6 meters. The transformer is an FT37-43 ferrite core wound with 10 bifilar turns of #26 enameled wire. The primary is just the single wire passing through the center of the toroid. To calibrate the SWR bridge, connect the output to a resistive 50-Ω load. Apply RF power on any HF band and adjust the 20-pF variable capacitor until the REFL LED goes out.

The FWD LED gives an indication of transmitter forward power. You may want to increase the value of the 4.7 kΩ resistor in the FWD circuit if the green LED is too bright. Or you could eliminate this LED and just use the REFL LED.

## A BAR-GRAPH DISPLAY FOR THE OPTICAL SWR METER

If you can supply dc power to your Z-Match Tuner and SWR meter, you may want to add the bar graph display as shown in Figure 4B to display SWR reflected power. A version of the tuner with bar graph option is shown in **Fig**ure **6** The nice thing about using the bar graph display is that it seems easier to null the reflected power because the display gives more of an analog meter "feel." Adjust the Z-Match tuner for minimum brightness of the REFL LED. When this occurs, the SWR should be less than 1.5:1.

This tuner addresses the issues of inductor size and finding reasonably priced multisection variable capacitors. The result is a wide-band, easily adjustable tuner for either portable or base station operation.

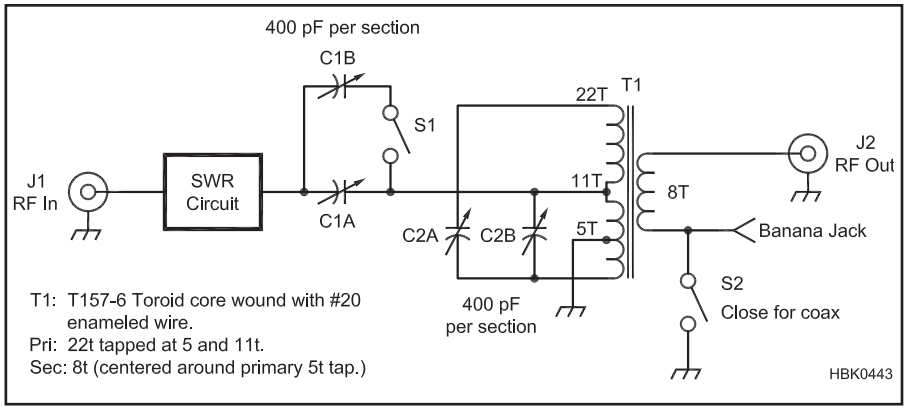

**Figure 2 –– Schematic of the 100-W Z-Match tuner.**

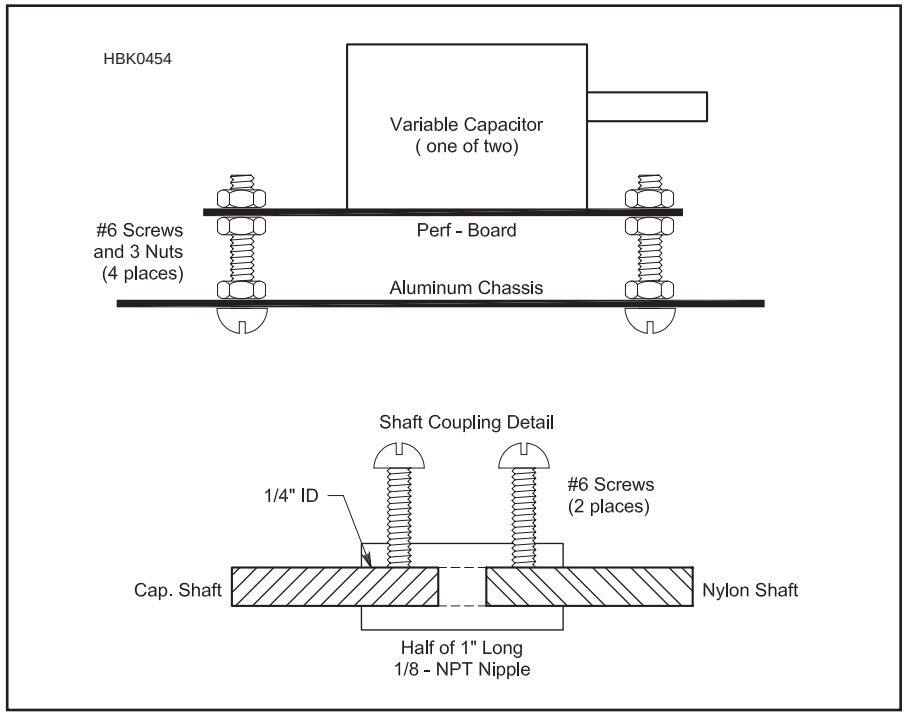
**C1, C2 — 400 pF per section, 2-section variable capacitor (Oren Elliott S2-399, www.orenelliottproducts.com). If you substitute another variable capacitor, use one with at least 350 pF per section, rated at 500 V RMS minimum.**
**J1, J2 — SO-239 connectors.**
**S1, S2 — SPDT mini-toggle switch.**
**T1 — Primary: 22 turns #20 AWG enam wire tapped at 5 and 11 turns. Secondary: 8 turns, with 4 turns either side of the primary 5 turn tap. Wound on T157-6 toroid (Amidon Associates, www.amidon-inductive.com).**
**Enclosure (Eagle, 40UB103 from www.mouser.com).**



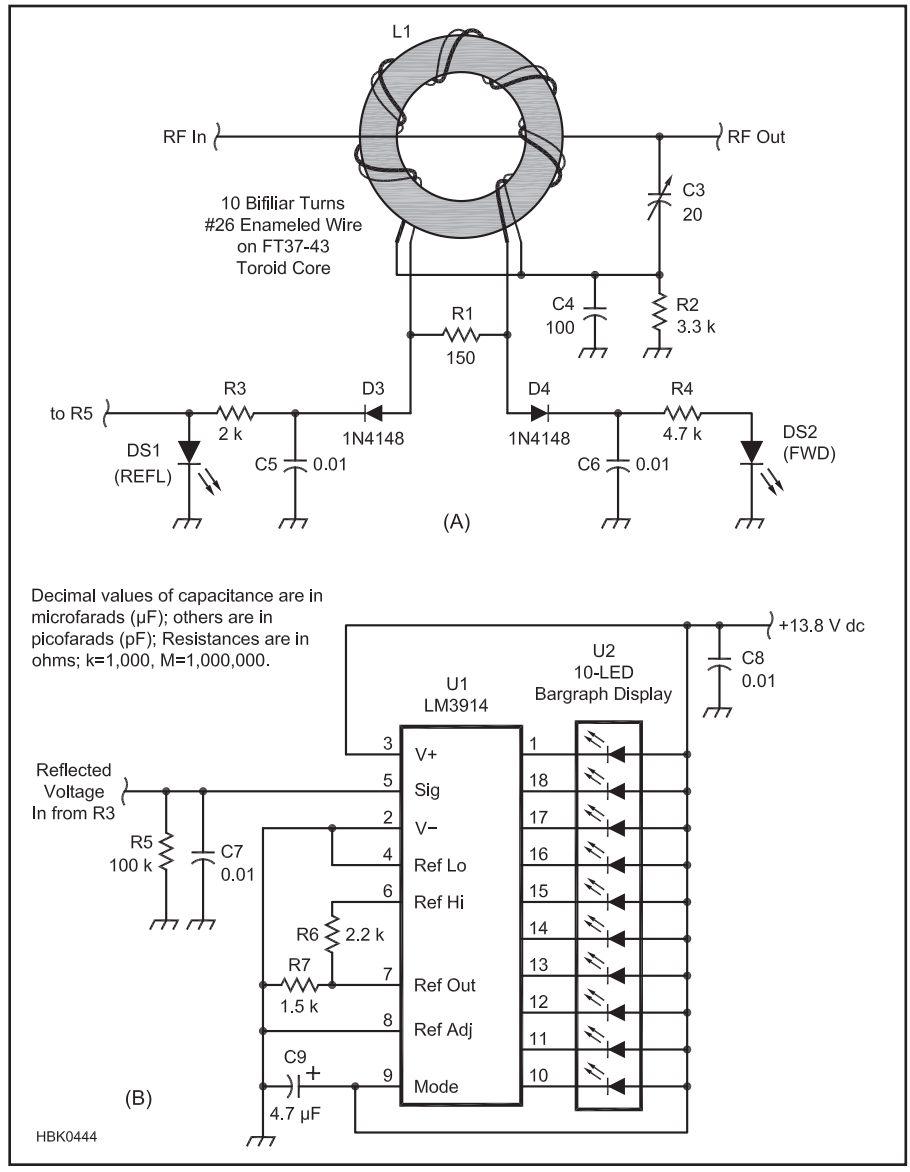


**Figure 3 –– The variable capacitors are insulated from the chassis by mounting them on perforated board. A 1/8-NPT nipple is made into a shaft coupling to couple the insulating shafts to the main capacitor shafts.**

**Figure 4 — Optical SWR meter schematic with the bar graph display modification (see text). The basic LED version is shown in A and the bar graph addition in B.**
**C3 — 2-20 pF variable capacitor (Mouser 24AA113 4-34 pF variable is suitable).**
**D1 — Red LED, high-intensity.**
**D2 — Green LED, high-intensity.**
**L1 — 10 bifilar turns of #26 enam wire on FT37-43 toroid core (Amidon Associates, www.amidon-inductive.com).**
**U1 — Display driver IC, LM3914 (All Electronics, www.allelectronics.com).**
**U2 — 10-LED bar graph display (Mouser 859-LTL-1000HR). Any 10-segment LED bar graph will work, but verify pinout.**

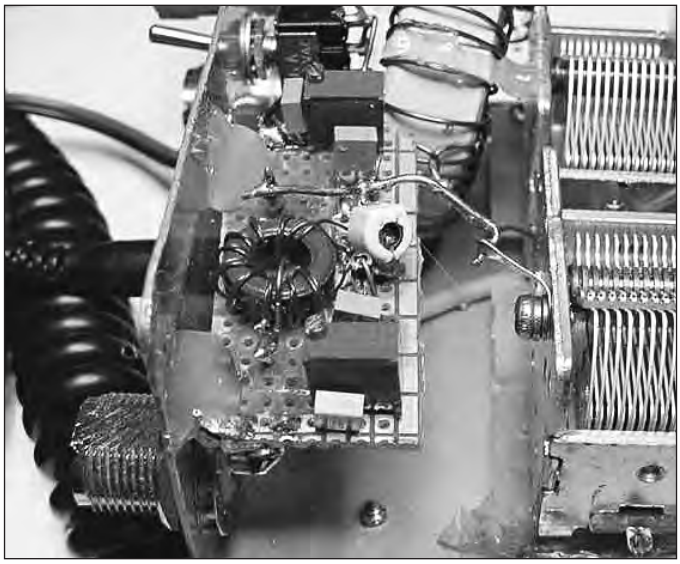

**Figure 5 –– The SWR meter circuit board is soldered directly to the RF input connector and attached to the back panel with hot glue.**

**Figure 6 –– The bar graph display of reflected power makes tuning easier and more intuitive.**

# 2 A Microprocessor Controlled SWR Monitor

This update of the basic SWR meter, designed by Larry Coyle, K1QW, uses a microprocessor to drive an analog panel meter, exploiting the best features of both analog and digital technology. The instrument also displays forward/reflected/net power and return loss (see the **Transmission Lines** chapter) with peak-hold capability. All display selections are selected by front panel switches. [*More information is available on K1QW's Web site, **www.lcbsystems.com**, and a complete package of information on this project with supporting files and photos is available with the downloadable supplemental content.*]

### OVERVIEW AND BLOCK DIAGRAM

After a bit of work, the author came up with the SWR/Power/Return Loss monitor shown in block diagram form in **Figure 7**. There are three interacting assemblies: SWR sense head, front panel assembly and signal processor board. (The latter two make up the Display and Signal Processor unit.) The SWR sense head is a conventional Stockton dual-transformer bridge with Schottky diode detectors. This component converts the forward and reflected RF amplitudes to dc and connects to the Display and Signal Processor by an ordinary stereo audio cable.

The user interface to the SWR monitor is familiar and intuitive. As you can see in **Figure 8A**, a front-panel rotary switch selects the quantity to be measured and an analog meter displays the result.

- Forward power on a linear scale
- Reflected power as a percentage of forward power
- Net power delivered to the load
- SWR on a linear scale
- Return loss on a linear scale

Some additional features are:

- Peak-hold front panel switch
- A front panel switch to multiply the meter sensitivity by 3X
- Data logging to a computer using the USB port.
- Transmitter Lockout (XLO) at high SWR

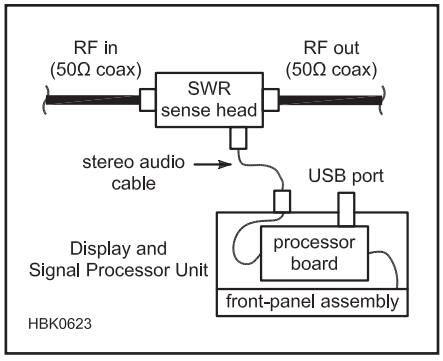
The rear panel, **Figure 8B**, shows the power switch and external connections

Transmitter Lockout (XLO) is a protective feature that lights a LED on the front panel and energizes a relay when the SWR exceeds a preset level. This opens a set of relay contacts which are connected to a pair of banana jacks on the rear panel. Once triggered, the relay remains energized for either three or nine seconds, depending on the configuration of the DIP switch located on the signal processor board. The same DIP switch also allows you to select the SWR level at which the XLO relay triggers — 1.5, 2, 3 or 4:1. By connecting the relay contacts in series with your rig's PTT or keying line, transmitting into high SWR can be prevented.

The two dc signals from the sense head make up the analog input to the signal processor board. The analog output for driving the meter is a pulse width modulated (PWM) signal generated by the microprocessor and smoothed by a simple resistor-capacitor (RC) filter.

### THE MICROPROCESSOR

The Parallax "Propeller" microprocessor (**www.parallax.com**) is unique in that it's really eight processors ("cogs") in one package, each one able to run its own separate program during its own time slot, controlled by a central "hub." This may sound challenging, but



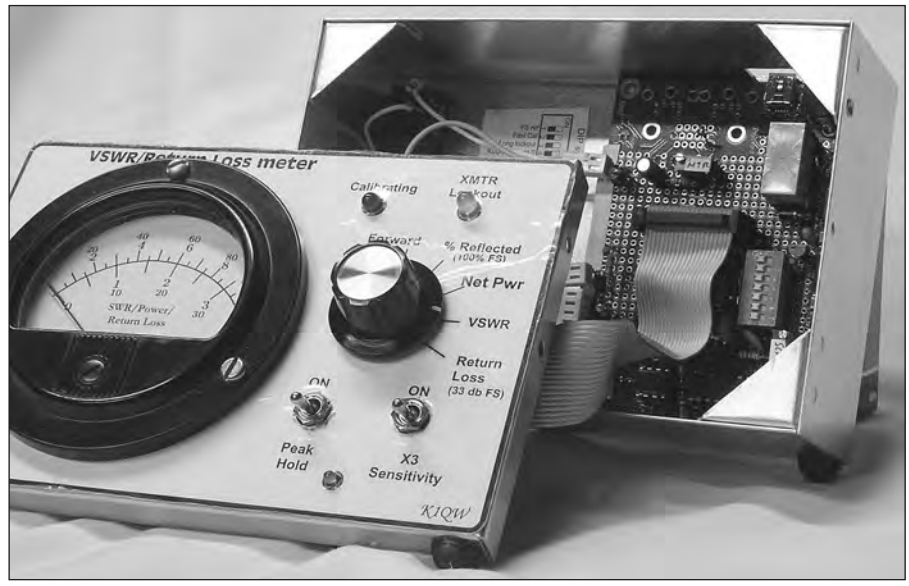


**Figure 7 — This block diagram shows how the SWR sense head and the signal processor box are connected by an ordinary two-conductor shielded stereo audio cable. The signal processor box contains the processor board and the front panel assembly.**

**(A)**

**(B)**

**Figure 8 — (A) Front panel of the display and signal processor unit. The meter face and the front panel lettering were created using Microsoft *Visio*, printed on heavy paper stock and attached with contact cement. With the front cover moved aside, you can see the ribbon cable carrying signals between the front panel assembly and the processor board. (B) Rear panel of the display and signal processor. The mini-B USB connector is accessible through the opening on the top surface of the enclosure.**

this actually makes programming the chip much easier. If you need to carry out several tasks at once — and most microprocessor applications do — just assign each job to its own individual cog and work on them separately. The central hub makes sure each cog gets its turn and keeps things synchronized.

The project uses the 3 × 4 inch Propeller USB Development Board from Parallax. It includes the Propeller chip, an Electrically-Erasable Programmable Read-Only Memory (EEPROM) for program storage, a 5 MHz crystal, two voltage regulators and, a USB mini-B connector with all the necessary USB interface circuitry.

The Propeller is programmed in a language called "Spin" which should make anyone who is familiar with the BASIC computer language feel at home. All the tools you need to write software for and to program the Propeller is available for free on the Parallax Web site, including an extensive library of pre-built code routines that you can just drop into your own programs.

Software is loaded onto the development board using the USB port from a host computer with a USB port. When not in use as a programming port, the same USB port is used as a serial data port for passing data between the SWR monitor and a computer running a terminal program such as HyperTerminal.

## MICROPROCESSOR BOARD CIRCUITRY

The development board includes a prototyping area large enough to hold all the parts of the SWR monitor except for front and rear panel components. Since most of the parts come assembled on the development board, construction of the digital board is quite easy. As you can see in **Figure 9A**, the electrical schematic, only two integrated circuits and a few analog components are required.

The dc signals representing forward and reflected power from the SWR sense head are received by dual op-amp U2. Each section of U2 is configured as a unity-gain voltage follower with a compensating diode (D1 and D2) to balance out the dc offset introduced by the Schottky rectifier diodes in the sensing head. (The technique of using a diode in the feedback path of an op amp to compensate for the non-linearity of an RF detector diode is described in detail in "A Compensated, Modular RF Voltmeter" in the **Test Equipment and Measurements** chapter of this book.) Each section also has an RC low-pass filter at its input to filter out unwanted RF — always a possibility around a ham shack.

The next stage in the signal path is U3, an analog multiplexer (MUX). This chip acts as a three-position switch under control of the microprocessor. (A fourth channel is unused.) The forward and reflected signals (on pins 14 and 15) are sampled alternately, 20 times per second, as long as the program is running. The third input to the MUX (pin 12) is grounded, and is also sampled by the microprocessor from time to time. This gives a measure of any dc offsets introduced by the analog-to-digital conversion and is used to correct the forward and reflected readings in software. This automatic zero adjustment takes place every five seconds or so and is indicated by a brief flash from the front-panel "Calibrating" LED that also serves as a "digital heartbeat" to show that the software is running.

The MUX output (pin 13) is passed to a potentiometer voltage divider to allow the scale factor to be set during calibration. From there it goes to the Propeller microprocessor itself where a delta-sigma analog-to-digital conversion takes place.

**Table 1A**
**Digital Inputs**

| *Digital Input* | *Originates at* | *What it does* |
|---|---|---|
| X3SEL | front panel - toggle switch | increases meter sensitivity by 3X |
| PEAKENBL | front panel - toggle switch | enables peak hold function on the meter |
| RLOSSEL | front panel – rotary switch | displays return loss on the meter |
| SWRSEL | front panel – rotary switch | displays SWR on meter |
| NETSEL | front panel – rotary switch | displays net power on meter |
| REFSEL | front panel – rotary switch | displays percent reflected power on meter |
| FWDSEL | front panel – rotary switch | displays forward power on meter |
| HIREFSEL | proc board - DIP switch | drives meter to full scale for calibration (must be OFF for normal operation) |
| FASTCAL | proc board - DIP switch | speeds up meter response for calibration (must be OFF for normal operation) |
| XLOLONG | proc board - DIP switch | enables long xmtr lockout (about 9 seconds) |
| XLTHRESH0 | proc board - DIP switch | XLO threshold bit 0 |
| XLTHRESH1 | proc board - DIP switch | XLO threshold bit 1 |
| XLOCKENBL | rear panel switch | enables xmtr lockout function |
| DIAG | proc board - jumper JP1 | displays raw input levels on terminal |
| W100 | proc board - jumper JP2 | changes terminal display to 0-100 watt range (required when using 100-watt sense head) |

**Table 1B**
**Digital Signals for SWR Threshold Select**

| *XLTHRESH1* | *XLTHRESH0* | *Selects SWR threshold level* |
|---|---|---|
| OFF | OFF | 1.5:1 |
| OFF | ON | 2:1 |
| ON | OFF | 3:1 |
| ON | ON | 4:1 |

## DIGITAL INPUT/OUTPUT

The microprocessor responds to the user's inputs by monitoring the state of 13 digital input pins. Most of these pins are controlled by the rotary and toggle switches on the front panel. The panel connects to the processor board by a short ribbon cable as shown in Figure 8A. See Figure 9B for a schematic of the separate front panel assembly. The ribbon cable also carries power for the LEDs.

On the processor board there are a multi-section dual in-line package (DIP) switch, S2, and two jumpers, JP1 and JP2, which select among the various operating modes. Lastly, the Xmtr Lockout (XLO) switch is mounted on the rear panel and visible in Figure 8B. These inputs to the microprocessor and the various modes of operation they control are summarized in **Table 1A**. The digital inputs are all active low; ie, the function is enabled when the signal line is at a low logic level. XLTHRESH1 and XLTHRESH0 form a two-bit code to select one of four SWR levels. When this SWR level is exceeded and if XLO is enabled, the transmitter lockout function is triggered.

There are only six digital *outputs*:

- Two address lines for the analog MUX to select among the three input channels
- Two lines to power the Calibrating and XLO LEDs located on the front panel
- One PWM signal to drive the front-panel analog meter
- One line to control the XLO relay.

Figure 8A shows the built-up processor board inside the 2 × 4 × 6 inch aluminum enclosure connected to the front panel with the ribbon cable. Here you can also see some of the wiring to the rear panel components. The USB connector is at the top edge of the circuit board and is accessible through a rectangular hole nibbled out of the top surface of the aluminum box.

## THE RF SENSE HEAD

The SWR sense head is the business end of the SWR meter where the forward and reflected amplitude components of the RF present on the transmission line are separated and converted to dc. For this project I adopted a straightforward Stockton directional

Transformers T1 and T2 are wound on FT50-43 ferrite toroid cores. For the 10-W sense head, use 10 turns of 24 AWG wire. For the 100-W head, use 31 turns.**

coupler circuit, with Schottky diode detectors and, unlike other designs, it requires no balancing trimmers. The schematic is given in **Figure 10** and the circuit is described in the article by J. Grebenkemper, KA3BLO, "The Tandem Match — an Accurate Directional Wattmeter," *QST*, Jan 1987, pp 18-26 (also published in the 2009 and earlier editions of *The ARRL Handbook*).

The accuracy of this circuit can be greatly improved by taking care to match the diodes in the sensing head with the corresponding compensation diodes in the op amp input stages on the signal processor board (D1 and D2 in Figure 9A). The easiest way to do this is with the diode test function included on most utility digital multimeters which passes a small dc current through the diode being tested and displays the forward voltage drop. The high-frequency range can be extended by using surface-mount components in the sensing head.

There are two versions of the SWR sensing head. The QRP version has a maximum range of 10 W. The other can handle up to 100 W. The only difference between the two versions is the number of turns on the toroid transformers (see the parts list in Figure 10). The high frequency performance of the 100-W head at 50 MHz proved to be poorer than the 10-W unit. I attribute this to the added capacitance of the transformer windings (the higher power transformers have three times as many turns as the low-power ones).

The overall accuracy of the monitor compares fairly well to commercial devices. **Figure 11A** and **11B** show performance data I took using dummy loads of 50 and 96.7 Ω. At five watts input, using the 10-W sensing head, the SWR readings were within 3% over a range of 1.8 to 30 MHz, and within 5% at 50 MHz. Figure 11B shows good accuracy down to 500 mW input (great for QRP rigs!) and is even usable down to 250 mW.

**Figure 11 — (A) SWR plotted against frequency, up to 50 MHz. (B) SWR as a function of input power level at a fixed frequency of 7.2 MHz. The data shown here were taken using the 10-W sense head, with dummy loads measured at 50 and 96.7 Ω.**

## 4.6 Software

For those who want to duplicate this project, the Spin language software listing, ready to program into the Parallax USB De-

velopment Board, is available in the package of supporting files with the downloadable supplemental content. There are also details of the subroutines handled by each of the Propeller cogs plus additional text and graphic files covering operation and features of the instrument.

As explained above, the organization of the Propeller into several peripheral processors (cogs) makes it easy to follow the program flow. The main program object (MAIN) runs in its own cog and is the first to be executed when power is applied (or whenever the chip is reset). Its first order of business is to set individual microprocessor pins to be inputs or outputs, as required.

Next, MAIN starts up three separate cogs for (1) analog-to-digital conversion (the ADC3CH cog), (2) generating the pulse width modulated waveform to drive the analog panel meter (the PWM cog) and (3) communicating with the terminal via the USB port (the MONITOR cog). They run continuously, swapping data with the MAIN program by means of variables stored in memory. After these three cogs are started, the MAIN program object enters a loop, endlessly repeating the following steps:

1) Read forward and reflected amplitudes and SWR data generated by the ADC3CH object.

2) Calculate forward power, percent reflected power, net power, SWR and return loss in decibels.

3) Display the quantity selected by the front panel switch on the panel meter using the PWM object.

4) Convert power levels, SWR and return loss information to ASCII strings and send them to the MONITOR object, which writes to the USB port.

This is a shining example of building on the accomplishments of others who have made their work freely available. Without such an extensive library of pre-tested routines on hand, the author probably would never have even started this project.

# 3 A 160- and 80-Meter Matching Network for Your 43-Foot Vertical

Many amateurs are using 43-ft vertical antennas for multiband operation. These antennas have higher radiation resistance than shorter verticals, which minimizes ground losses. This is especially important when you have an electrically short antenna — a characteristic of even a 43-ft antenna on 160 and 80 meters.

When fed with a 1:4 unun (unbalanced-to-unbalanced transformer), a 43-ft antenna has a reasonable compromise SWR on 60-10 meters, which means that cable and unun losses are pretty much negligible on these bands. Performance on 160 meters, and to a lesser extent on 80 meters, is not as good unless you provide matching right at the antenna. The high capacitive reactance and low radiation resistance of a 43-ft antenna on 160 and 80 meters make the mismatch so bad that it is almost impossible to match from your shack if you are using low-loss coax. If you can match the antenna system from your shack, you will lose a lot of power in your coax and unun because of the very bad mismatch at the antenna. Phil Salas, AD5X, describes two impedance matching devices for use with 43-ft verticals designed to significantly reduce SWR-related losses and to "help out" inside tuners on 160 and 80 meters.

### THE MATCHING REQUIREMENT

Antenna analyzer measurements of the author's 43-ft vertical antenna indicate a capacitive reactance of about 580 Ω on 160 meters. This value will vary with different kinds of 43-ft verticals, proximity to other objects and other factors unique to each installation but is usually in the 550-650 Ω range. With this amount of capacitive reactance, approximately 50 µH of inductance is needed to resonate the antenna. On 80 meters, approximately 9 µH is needed. A 50 µH high-Q inductor is large, but a toroidal inductor will be more compact.

**Figure 12** shows the circuit of a compact design that handles 1500 W SSB or CW on 80 and 160 meters. **Table 2** lists the necessary parts. The inductor consists of 35 turns of #14 AWG solid copper insulated house wiring wound on a T400A-2 toroid core, with the feed tapped 2 turns from the ground end for 80 meters, and 3 turns from the ground end for 160 meters. Start with 38 turns and then remove turns as necessary to get the network to resonate where you want it in the 160 meter band (more on this later).

The toroid assembly fits in a 6 × 6 × 4-inch NEMA enclosure. The assembly is secured with a 2.5-inch long #10 screw and associated hardware along with a 2 × 4 inch piece of unplated fiberglass PC board material (**Figure 13**). Before mounting the toroid, prepare it by scraping the insulation off the outside of the wire at turns 2, 3 and 11-13. Because of the high voltages possible with 1500 W (especially on 160 meters), wrap the toroid with two layers of 3M #27 glass-cloth electrical tape for added insulation between the wire and the toroid core.

To select between 160- and 80-meter operation, the appropriate connections are made with external jumpers across binding

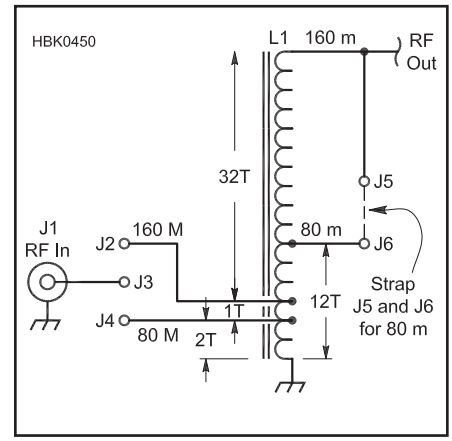

**Figure 12 — 160/80-meter impedance matching network for use with a 43-ft vertical. See Table 2 for a parts list.**

| 1 | SO-239 connector (J1) | Mouser 601-25-7350 |
| 4 | Black binding post (J2, J4-J6) | Mouser 164-R126B-EX |
| 1 | Red binding post (J3) | Mouser 164-R126R-EX |
| 4 | Banana plug | Mouser 174-R802-EX |
| 1 roll | 3M #27 glass tape (for L1) | Hardware store/home center |

Misc: #14 AWG house wiring, stainless steel hardware.

posts as shown in **Figure 14**. Stainless steel #8 hardware (screws, washers, lockwashers, nuts) is used for the matching unit ground and RF output. Internal to the matching unit, a 2-inch-wide strip of aluminum duct repair tape makes a good low-impedance ground between the coax connector and the ground screw on the bottom of the case. Finally, use #14 AWG stranded insulated wire for all internal connections.

## TUNING THE MATCHING NETWORK TO RESONANCE

Your particular installation will almost certainly require you to change the resonant frequency of the matching network. This is because there will be variations of the antenna impedance based on your particular installation and desired operating frequency range. The design is such that the overall inductance is too large for 160 meters, so the network should resonate at or below the lower band edge. Therefore, you will need to remove one or more of the upper inductor turns to resonate the network for the desired frequency on 160 meters. To do this, first solder wires from the turn 2 and 3 tap points on the coil to the two outer binding posts by the RF IN connector. The input tap points tend to be fairly non-critical and will probably always be the same for all installations.

Now solder a short wire from the RF IN center pin to the middle binding post. Next, externally jumper the middle binding post to the 160 meter binding post (turn 3). Connect the matching assembly to the base of your 43-ft vertical and use an antenna analyzer to find the minimum SWR point on 160 meters. If the resonant frequency is too low, remove a turn of wire and measure again. You should see a 50 kHz upward move in frequency per turn of wire removed.

When you have reached the desired resonant point on 160 meters, it is time to move to 80 meters. Externally jumper the input tap middle binding post to the 80-meter binding post (turn 2), and use a clip lead to short from the top of the coil to about turn 12. Again, find the frequency where minimum SWR occurs. Move the tap point up or down until you reach the desired resonance point. Solder a wire from this tap point to one of the binding posts. Solder another wire from the top of the coil to another binding post. Now you will be able to externally jumper these binding posts to go from 160 to 80 meters.

**Figure 15** shows the author's final results for 160 and 80 meters as measured with an antenna analyzer connected directly to the matching network input at the base of the antenna. With resonance set for the CW end of these bands, the 2:1 SWR bandwidth on 160 meters is about 50 kHz and about 150 kHz on 80 meters. Even a 3:1 SWR on these bands results in negligible SWR-related cable losses and is easily matched with an in-shack tuner.

## OPERATION

Using the matching unit is simple. Just disconnect your normal unun when you want to operate on 160 or 80 meters and connect this matching unit to the base of the antenna. Select either 160 or 80 meters with the external straps. You can connect both the unun and this matching unit to the antenna at the same time, and just leave off the ground wire from the unit that is not used. The matching unit connected to the base of a 43-ft vertical is shown in **Figure 16**.

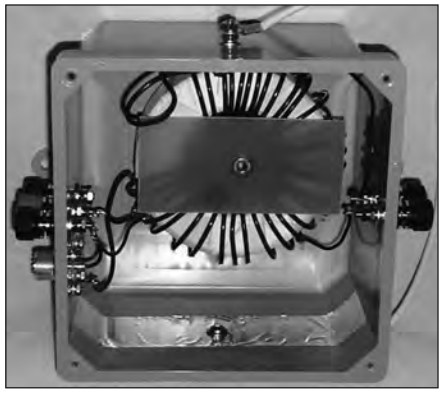

**Figure 13 — Mounting details of the toroidal inductor for the 160/80-meters matching unit. The input side of the enclosure is on the left. Coax to the station connects to the RF IN SO-239, and a strap between the center binding post and one of the outer posts selects the input tap for operation on 160 or 80 meters. On the right side, a jumper between the two binding posts shorts a section of the coil for 80-meter operation. The RF OUT connection to the base of the antenna is made with via the #8 machine screw and hardware at the top, and the ground connection is on the bottom.**

**(A)**

**(B)**

# 4 Switching the Matching Network for Your 43-Foot Vertical

Another project in this chapter describes a simple 160 and 80 meter impedance matching network for installation at the base of a 43-ft vertical antenna. While that unit is very effective and inexpensive to build, it is also a little inconvenient in that you must connect it when it is needed, and you must also manually enable 160 or 80 meter operation using jumpers. Phil Salas, AD5X, enhances the original design with a more versatile matching assembly that can be controlled remotely for operation on all bands.

## FIRST — A WORD ABOUT RF VOLTAGES

This unit uses relays for selecting the different bands, so a discussion of RF voltages is appropriate. RF voltages at the base of an untuned vertical can be quite high. As the antenna becomes shorter, the capacitive reactance becomes higher and so the resultant voltage drop across the combination of reactance and radiation resistance increases. With the 43-ft vertical, the worst-case situation will occur on 160 meters where the capacitive reactance is approximately 600 Ω. The radiation resistance is approximately 3 Ω.

With a perfect ground (no ground loss) and 1500 W of power properly matched to the antenna, peak RF voltage works out to about 19,000 $V_{pk}$:

$$I = \sqrt{1500\ W / 3\ \Omega} = 22.4\ A$$

$$|Z| = \sqrt{3^2 + 600^2} = 600\ \Omega$$

$$V_{RMS} = 22.4 \times 600 = 13{,}440\ V$$

$$V_{pk} = 13{,}440 \times 1.414 = 19{,}004\ V$$

Very few hams have a ground system that is lossless. With a ground loss of 10 Ω (better than most hams have), it works out to about 9100 $V_{pk}$. With the author's 600-W amplifier, assuming a ground loss of 10 Ω, it's about 5800 $V_{pk}$.

The author experimented with two different relays from Array Solutions. The RF-10 DPDT relay has 1.7 $kV_{pk}$ contact-to-contact and 3.1 $kV_{pk}$ contact-to-coil voltage breakdown ratings. This relay proved to be a good solution for up to about 500 W on 160 meters when the two sets of contacts are put in series. The second relay is the RF-3PDT-15 which has 3.1 $kV_{pk}$ contact-to-contact and 5.3 $kV_{pk}$ contact-to-coil voltage breakdown ratings. This relay has nearly twice the contact breakdown rating of the RF-10, and it's 3PDT so an additional set of contacts can be put in series to increase the breakdown voltage. This relay can be used in a full legal limit application if applied properly in the circuit (more on this later).

Depending on your power level and ground losses, the less expensive and smaller RF-10 may be all you need. Make the calculations to determine which relay is more appropriate for you. If you look for alternative relays, pay attention to the breakdown voltage rating; it's hard to find relays with suitable ratings for this application. The Array Solutions relays have 30 A contacts, but 15 A or more should be sufficient.

## THE ALL-BAND MATCHING SOLUTION

As explained in the companion project describing a simple matching network, when fed with a 1:4 unun (unbalanced-to-unbalanced transformer), a 43-ft antenna has a reasonable compromise SWR on 60-10 meters. The antenna requires approximately 50 µH of inductance to resonate on 160 meters and 9 µH on 80 meters. For convenient all-band operation from the shack, the solution shown in **Figure 17** uses two relays to switch in the unun for 60-10 meter operation or the appropriate inductance for 160 and 80 meters. The unit will handle up to 1500 W from 160-10 meters.

Relay control requires inputs of 0 V, +12 V dc or –12 V dc. The matching unit operates as follows:

- With no control voltage applied, the 1:4 unun is connected to the antenna for 60-10 meter operation, and the inductor is disconnected, so the original antenna compromise SWR on these bands is preserved.
- With +12 V applied for 80-meter operation, K1 and K2 close. Contact K1C connects the unun secondary to L1 through K2C at the 200 Ω point (6 turns from the ground end). Contacts K2A and K2B short out the top part

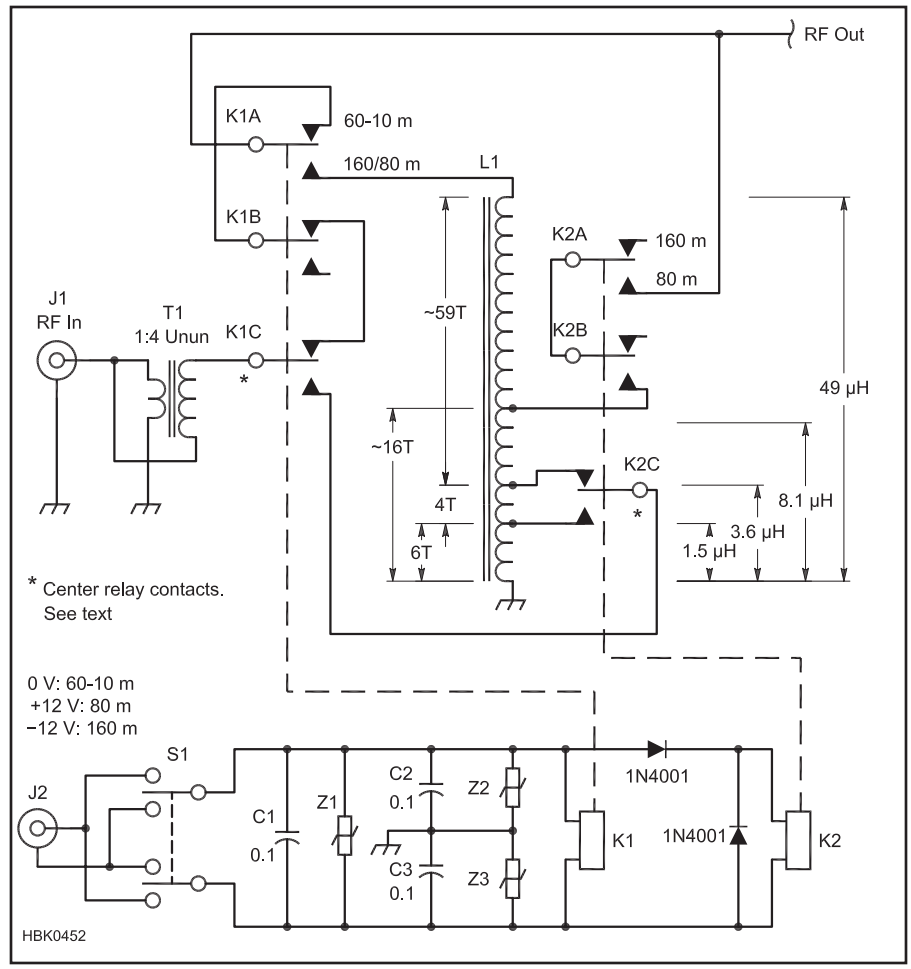

**Figure 17 — This switched impedance matching network for use with a 43-ft vertical allows operation on 160-10 meters and is controlled from the station operating position. See Table 3 for a parts list.**

of L1 (about 16 turns from the ground end), resonating the antenna on 80 meters.

• When the voltage is reversed (–12 V) for 160-meter operation, K1 stays closed but K2 opens. K2C now connects the unun secondary to L1 at the 200 Ω point for 160 meters (10 turns from the ground end). Contacts K2A and K2B open, removing the short and allowing the entire coil to be used to resonate the antenna on 160 meters.

Connecting the unun to L1 at the 200 Ω point keeps the unun secondary voltage reasonable, and the feed line and unun losses very low as well.

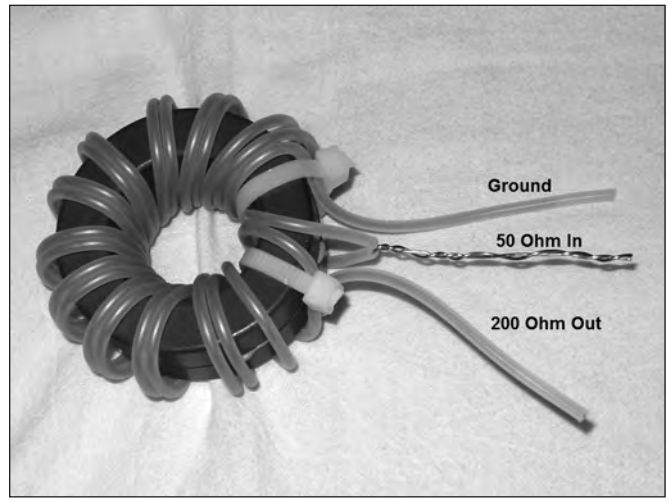

**Figure 19 — Connections for a voltage unun (MFJ 10-10989D shown).**

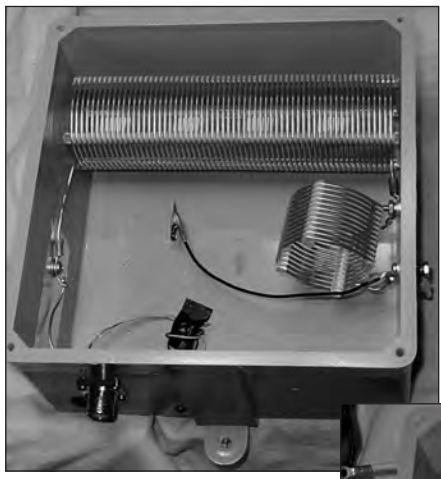
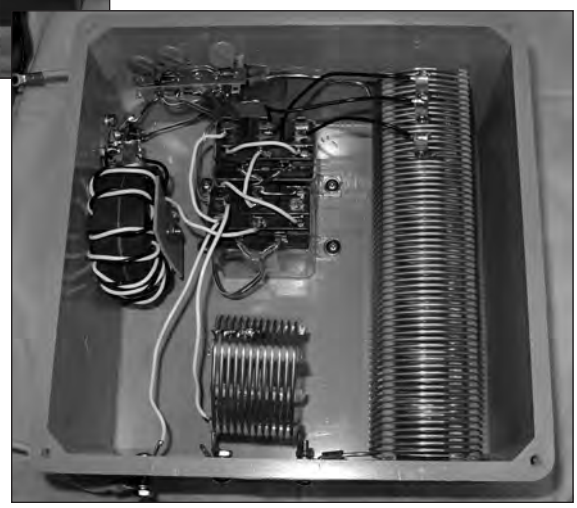


## CONSTRUCTION

**Figure 18** shows the layout. The matching unit is built in 8 × 8 × 4-inch NEMA weatherproof box available from most home centers. The author used an MFJ 404-0669 air-wound coil, and this box is too small to fit the entire inductor length needed. The inductor is split into two pieces; the long section consists of 61 turns, and the short section consists of 12 turns. As drawn in the schematic, the longer coil section is at the "bottom" (one end connects to ground), while the shorter coil is at the "top" (one end connects to RF OUT). If you have room for a larger box, a 12 × 12 × 4-inch NEMA box fits the full inductor length without cutting.



Two Array Solutions RF-3PDT-15 relays are mounted to the case next to each other in the upper center. These are enclosed relays with all connections on one side, making for easy assembly. The 2.1 × 5.5 mm dc power jack and SO-239 RF IN connector are in the upper left corner. The MOVs and bypass capacitors for the control line are mounted on a terminal strip near the power connector.

The unun is mounted to the side of the enclosure using a machine screw and a piece of PC board material with the copper removed. The antenna is unbalanced, so a current balun or voltage unun (*not* a voltage balun) is typically used. A voltage unun should be wired as shown in **Figure 19**.

All internal wiring consists of insulated #14 AWG stranded wire. Attach the wires to the coil tap points using the MFJ coil clips called out in the parts list. (You can solder the wires directly to the coil, but this is difficult because of the size of the coil wire and the spacing of the turns.) Use #8 stainless steel screws, washers, lock-washers and nuts for coil mounting, and for the ground and RF OUT (antenna feed) terminals. **Table 3** lists the parts and part sources.

(A)

(B)

**Figure 18 — Inside the enclosure. At A, the air-wound inductor has been cut into two pieces (see text) and mounted. The wire from the shorter piece will attach to the RF OUT terminal. At B, the other components have been added. The unun is mounted on the left side of the case. The relays are at the top center, and the MOVs and bypass capacitors are mounted on a terminal strip at the upper left, next to the RF IN and dc control connectors.**

### Relay Connections

As discussed earlier, the voltage across the full coil can be very high on 160 meters. Connecting the relay contacts in series as shown in the schematic increases the overall breakdown voltage. Also, the tap points on the inductor provide additional voltage-above-ground, which helps with the overall breakdown voltage.

The main concern is with the contact-to-coil breakdown rating of 5.3 kV peak. The

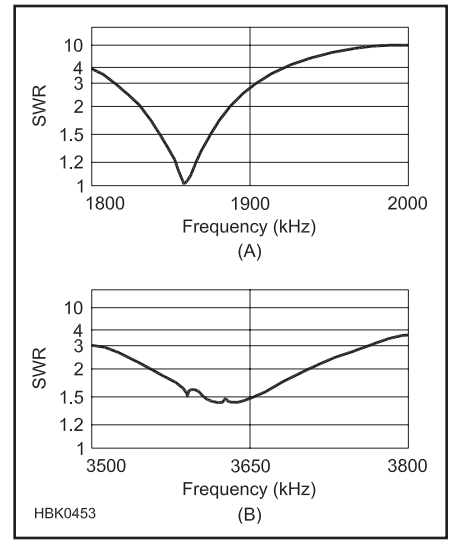


**Figure 20 — Measured at the antenna base, the 2:1 SWR bandwidth is about 50 kHz for 160 meters and 150 kHz for 80 meters.**

Misc: #14 AWG house wiring, stainless steel hardware.

outer contacts are connected via insulated internal wires that are well separated from the coil by 0.1-0.2 inch. The problem is with the common wire for the center contacts, which is in contact with the coil. While the coil and common wire are both insulated, there is no air gap separation between them; this close proximity is what determines the relay breakdown voltage rating. Wired as shown in Figure 17, the center relay contacts are used for the lowest voltage points.

The switched control voltage input uses a 12-V, 1-A wall transformer supply. It's a good idea to keep the ±12 V control voltages separate and isolated from the regular station power supply to eliminate any possibility of shorting the main power supply when the control voltage polarity is flipped. The switching is easily done with a DPDT center-off switch (S1).

**Figure 21 — The switchable matching unit mounted at the base of the author's 43-ft vertical.**

## MATCHING NETWORK RESONANCE

Some initial adjustment is required to tune the resonant frequency of the matching network to account for variations in the antenna impedance based on your particular installation and desired operating frequency range. The overall starting inductance is too large for 160 meters, so the network will resonate at or below the lower band edge. Therefore, you can simply short one or more turns at the upper (RF OUT) end of the inductor to tune the network higher in frequency.

For the initial adjustments, don't connect the wire leads that attach between the relay contacts and the tap points on the coil. Instead, build short jumpers using the test clips and micro clips (perfect for the coil turn taps) called out in the parts list, and attach these between the relay contacts and coil using the suggested tap points shown on the schematic.

Next, connect the matching assembly to the base of your 43-ft vertical, enable 160 meter operation by applying –12 V dc and jumper turns from the RF OUT end of the inductor with a short clip lead until you find the desired 160 meter resonance point. Next, move the 160 meter relay tap point (from the unun secondary through K2C) until you get minimum SWR. (The starting point is 10 turns from the ground end.) Now permanently short the inductor turns by soldering a piece of #16 AWG buss wire across them. As shown in the photos, the author needed to short six turns (on the short coil).

Next apply +12 V to the relay assembly to enable 80-meter operation. Select the coil shorting point (from K2B — start 16 turns from the ground end) for your desired resonant frequency. Then adjust the tap point (from K2C — start 6 turns from ground) for best SWR. Finally remove the test clips leads, attach the coil clips, and solder wires between the coil clips and relay.

**Figure 20** shows the results for 160 and 80 meters as measured with an antenna analyzer connected directly to the matching network input at the base of the author's antenna. With resonance set for the CW end of these bands, the 2:1 SWR bandwidth on 160 meters is about 50 kHz and about 150 kHz on 80 meters. Even a 3:1 SWR on these bands results in negligible SWR-related cable losses and is easily matched with an in-shack tuner.

## OPERATION

Operation of this matching unit couldn't be simpler. When no control voltage is applied, the unun is connected and the antenna functions as it always has on 60-10 meters. For 80-meter operation, apply +12 V dc, and for 160-meter operation apply –12 V dc. The matching unit connected to the base of the author's 43-ft vertical is shown in **Figure 21**.

The matching network discussed in this article will permit very effective operation of your 43-ft vertical on all bands from 160-10 meters. Feel free to experiment a little. You might prefer to use the toroid from the basic matching network in the companion project instead of the air-core inductor. And if you are not running more than about 500 W, the less expensive RF-10 relays are all you need.

# 5 An External Automatic Antenna Switch for Use With Yaesu or ICOM Radios

This antenna-switching-control project involves a combination of ideas from several earlier published articles.[1,2,3] This system was designed to mount the antenna relay box outside the shack, such as on a tower. With this arrangement, only a single antenna feed line needs to be brought into the shack. **Figure 22** shows the control unit and relay box, designed and built by Joe Carcia, NJ1Q. Either an ICOM or Yaesu HF radio will automatically select the proper antenna. In addition, a manual switch can override the ICOM automatic selection. That feature also provides a way to use the antenna with other radios. The antenna switch is not a two-radio switch, though. It will only work with one radio at a time.

Many builders may want to use only the ICOM or only the Yaesu portion of the interface circuitry, depending on the brand of radio they own. The project is a "hacker's dream." It can be built in a variety of forms, with the only limitations being the builder's imagination.

## CIRCUIT DESCRIPTION

**Figure 23** is a block diagram of the complete system. An ICOM or Yaesu HF radio connects to the appropriate decoder via the accessory connector on the back of the radio. Some other modern rigs have an accessory connector used for automatic bandswitching of amplifiers, tuners and other equipment. For example, Ten-Tec radios apply a 10 to 14-V dc signal to pins on the DB-25 interface connector for the various bands. Other radios use particular voltages on one of the accessory-connector pins to indicate the selected band. Check the owner's manual of your radio for specific information, or contact the manufacturer's service department for more details. You may be able to adapt the ideas presented in this project for use with other radios.

A single length of coax and a multiconductor control cable run from the rig and decoder/control box to the remotely located switch unit. The remote relay box is equipped with SO-239 connectors for the input as well as the output to each antenna. You can use any type of connectors, though.

ICOM radios use an 8-V reference and a voltage divider system to provide a stepped band-data output voltage. **Table 4** shows the output voltage at the accessory socket when the radio is switched to the various bands. Notice that seven voltage steps can be used to select different antennas. The ICOM accessory connector pin assignments needed for this project are:

| | |
|---|---|
| Pin 1 | +8 V reference |
| Pin 2 | Ground |
| Pin 4 | Band signal voltage |
| Pin 7 | +12 (13.8) V supply |

Yaesu radios provide the band information

| 28 | 5V | 0V | 0V | 5V | 9 |

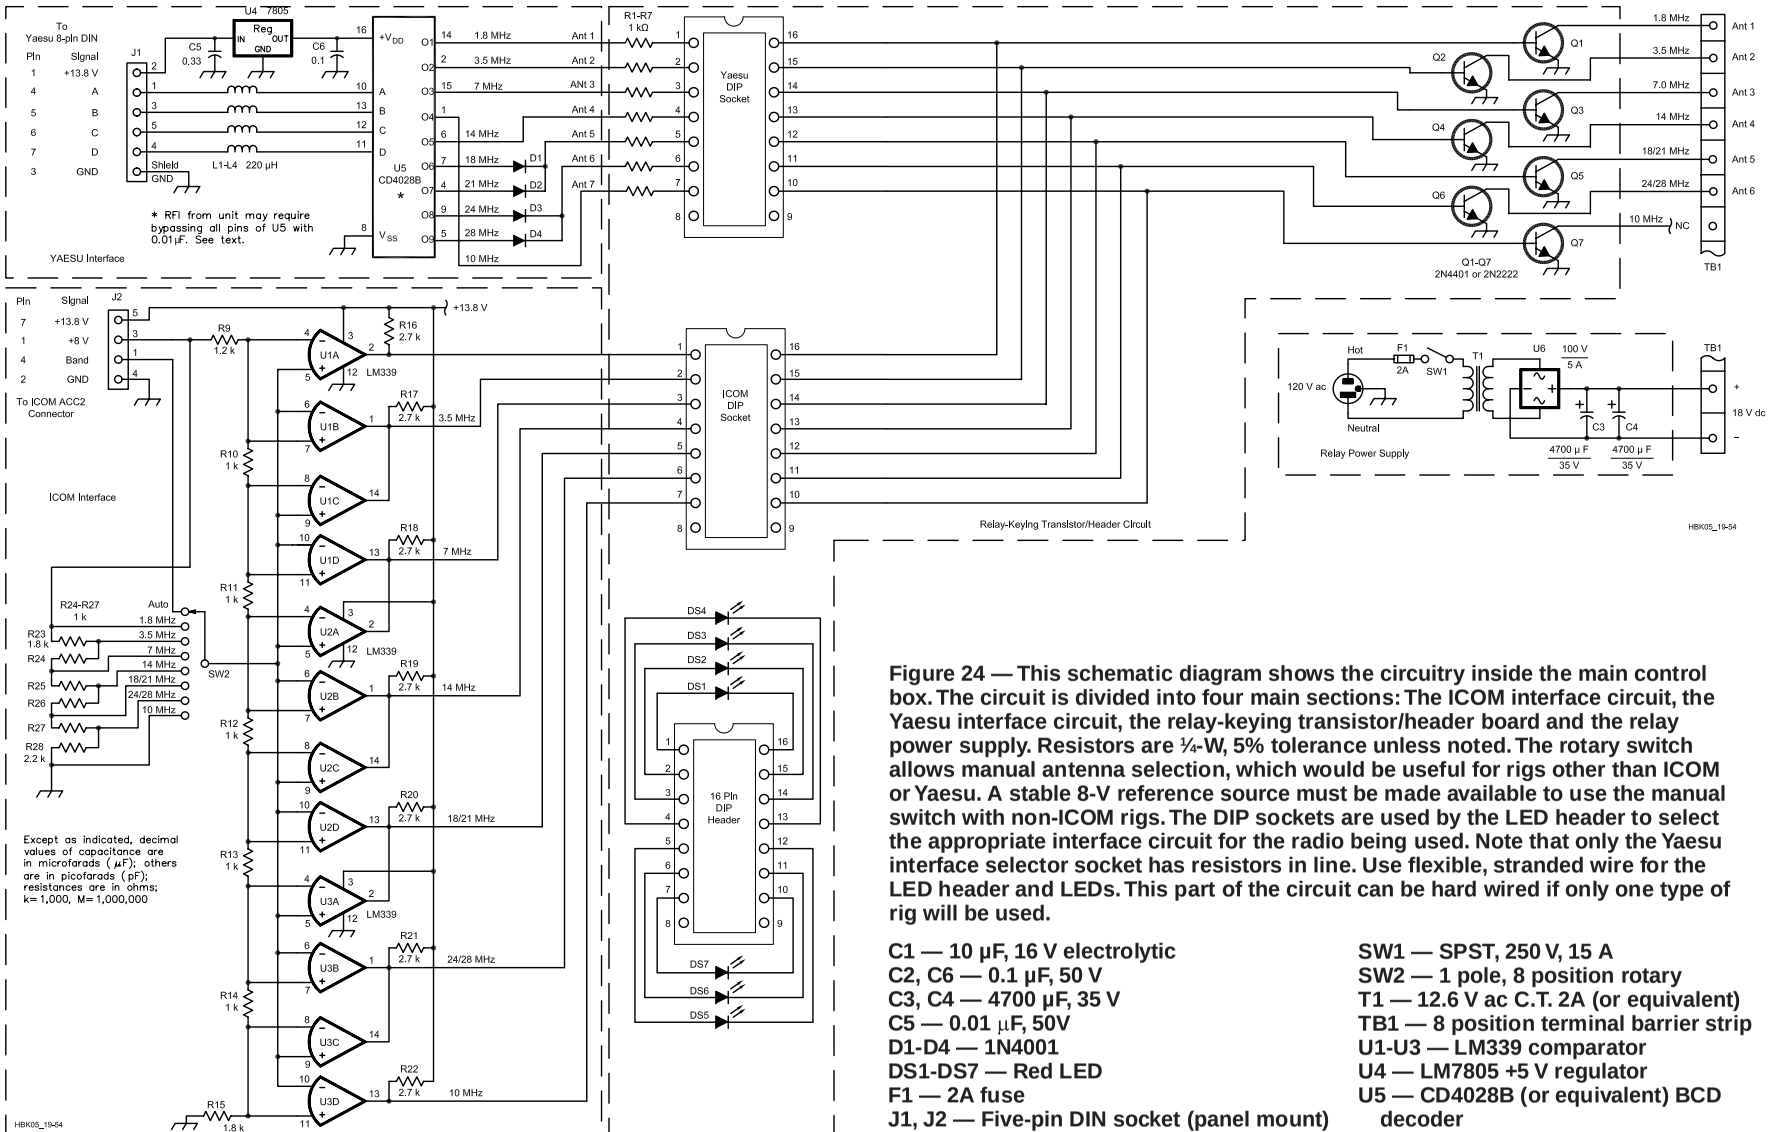

**Figure 24 — This schematic diagram shows the circuitry inside the main control box. The circuit is divided into four main sections: The ICOM interface circuit, the Yaesu interface circuit, the relay-keying transistor/header board and the relay power supply. Resistors are ¼-W, 5% tolerance unless noted. The rotary switch allows manual antenna selection, which would be useful for rigs other than ICOM or Yaesu. A stable 8-V reference source must be made available to use the manual switch with non-ICOM rigs. The DIP sockets are used by the LED header to select the appropriate interface circuit for the radio being used. Note that only the Yaesu interface selector socket has resistors in line. Use flexible, stranded wire for the LED header and LEDs. This part of the circuit can be hard wired if only one type of rig will be used.**

as binary coded decimal (BCD) data on four lines. Nine different BCD values allow you to select a different antenna for each of the MF/HF bands. **Table 5** shows the BCD data from Yaesu radios for the various bands. The Yaesu 8-pin DIN accessory connector pin assignments needed for this project are:

Pin 1 +12 (13.8) V supply
Pin 3 Ground
Pin 4 Band Data A
Pin 5 Band Data B
Pin 6 Band Data C
Pin 7 Band Data D

**Figure 24** is the schematic diagram for the control box. We will discuss each part of the control circuit later in this description. First, let's turn our attention to the external antenna box.

## EXTERNAL ANTENNA BOX

Only the number of control lines going out to the relay box limits the number of antennas this relay box will switch. The unit shown in the photos has 10 SO-239 connectors, to switch the common feed line to any of nine antennas. Many hams will use an eight-conductor rotator cable (such as Belden 9405) to the relay box. Using eight wires, we can control seven relays (six for antennas and one to ground the feed line for lightning protection) plus the relay coil power supply and ground lead. The photos show eight relays, and the box can be expanded further if desired. There is also a connector for power and control lines. Use of a DB-15 allows for the addition of more relays and control lines later. A DB-9 connector would be suitable for use with the eight-conductor control cable, or you may wish to use a weatherproof connector. **Figure 25** shows the relay box schematic diagram.

Since the box will be located outside, use a weatherproof metal box — a Hammond Manufacturing, type 1590Z150, watertight aluminum box is shown. It's about 8.5×4.25×3.125 inches. This is a rather hefty box, meant to be exposed to years of various weather conditions. You can, however, use almost anything.

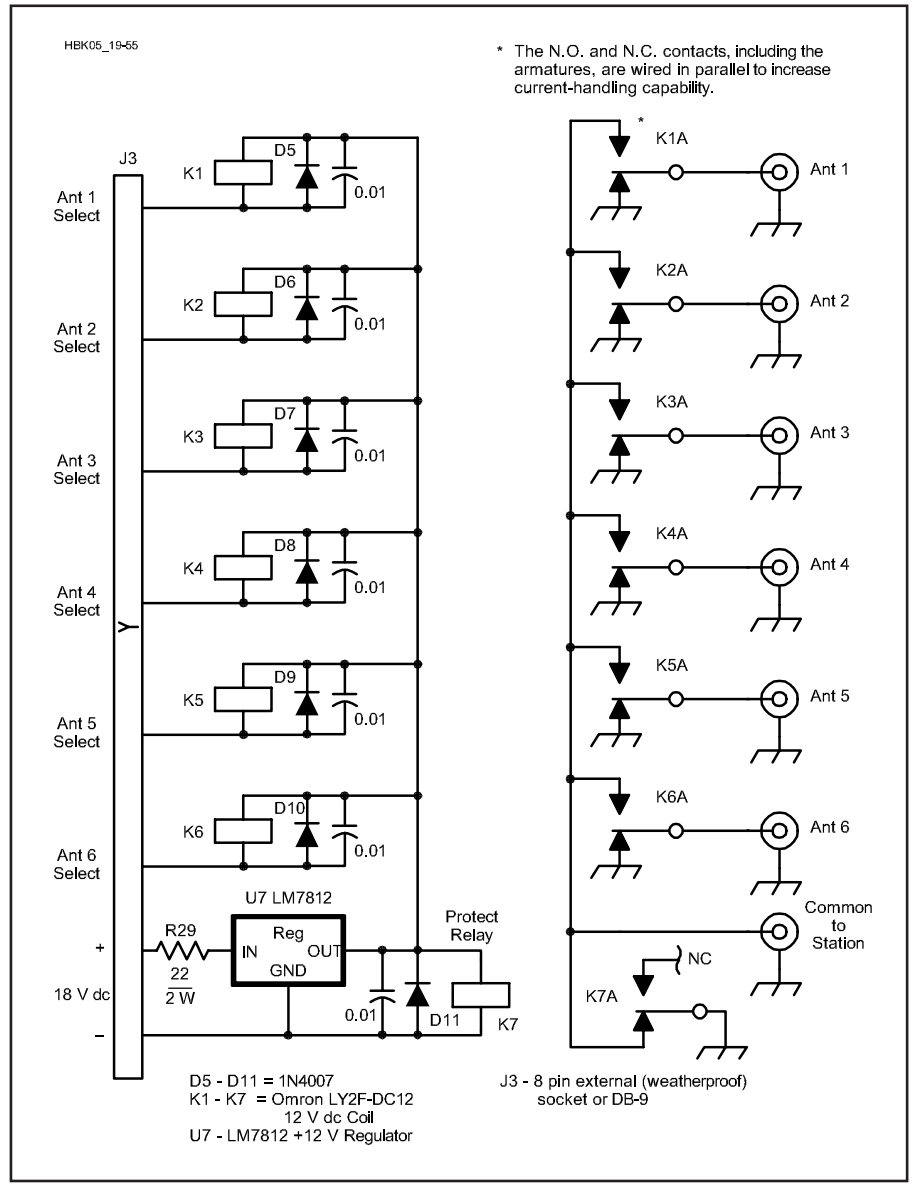
The coax connectors are mounted so each particular antenna connector is close to the relay, without too much crowding. For added weather protection (and conductivity), apply Penetrox to the connector flange mount, including the threads of the mounting screws. On the power/control line connector, use Coax Seal or other flexible cable sealant.

The aluminum angle stock on either side of the box is for mounting to a tower leg. The U-bolts should be of the proper size to fit the tower leg. They should also be galvanized or made of stainless steel.

## ANTENNA RELAYS

One of the more difficult parts of this project was the modification of the relays (DPDT Omron LY2F-DC12). To improve isolation, the moveable contacts (armature) are wired in parallel and the connecting wire is routed through a hole in the relay case.

Remove the relay from its plastic case. Unsolder and remove the small wires from the armatures. Carefully solder a jumper across the armature lugs with #20 solid copper. Then solder a piece of very flexible wire (such as braid from RG-58 cable) to either armature lug. Obviously, the location of the wire depends on which side you wish to connect the SO-239. You will also need to make a hole in the plastic case that is large enough to accommodate the armature wire without placing any strain on the free movement of the armature. Slip a length of insulating tubing



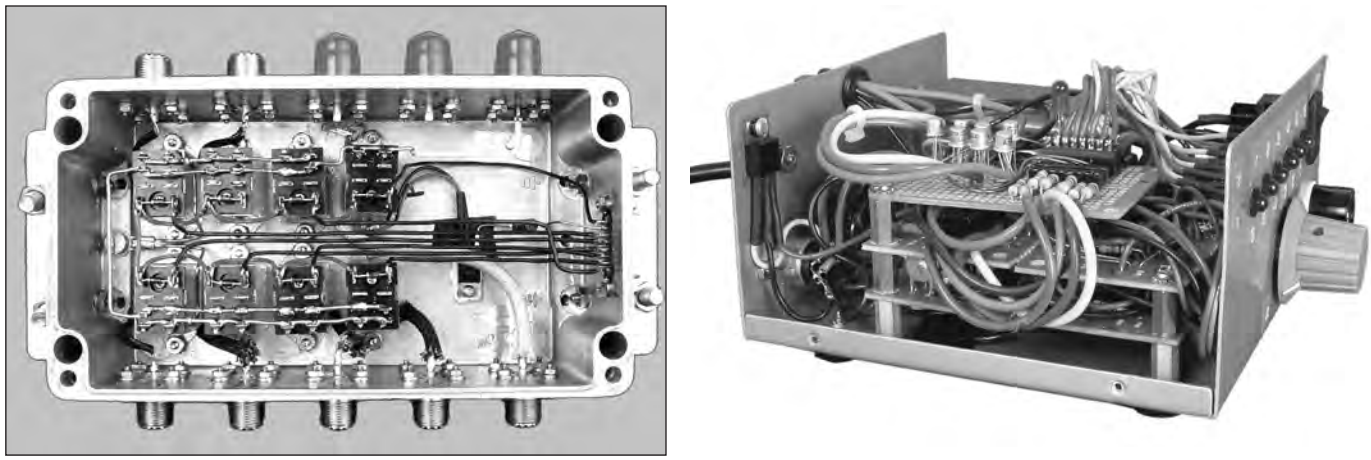


**Figure 25— The schematic diagram for the external antenna relay box. All relays are DPDT, 250 V ac, 15 A contacts. R29 is used to limit the regulator current. Mount the regulator using TO-220 mounting hardware, with heatsink compound. With the exception of the normally closed and normally open contacts, all wiring is #22 solid copper wire.**

**D5-D11 — 1N4007.**
**J3 — 8 pin external weatherproof connector (or DB-9 with appropriate weather sealant).**
**K1-K7 — Omron LY2F-DC12 with 12 V coil.**
**U7 — LM7812 +12 V regulator.**

(A) (B)

**Figure 26 — At A, the external relay box. The LM7812 regulator is mounted to the bottom of the box. The relay normally open and normally closed contacts are wired in parallel using #12 solid copper. The two extra flange-mount SO-239 connectors at the upper right are for future expansion. At B, inside the control box. The bottom board in the enclosure, as well as the right half of the middle section, hold the ICOM circuit. The Yaesu interface is on the left side of the middle section. The top circuit board holds the DIP sockets and relay-selection transistors. All high voltage leads are insulated. The 7805 5-V regulator is mounted on the back panel using TO-220 mounting hardware, with heatsink compound.**

over this wire to prevent it from shorting to the aluminum box.

The normally open and normally closed contacts are also wired in parallel. This can be done on the lugs themselves. For this, use #12 solid copper wire.

Mount the relays in the aluminum box, oriented so they can be wired together without difficulty. (See **Figure 26A**.) With the exception of the wire used for the relay coils (#22 solid wire), use #12 solid copper wire for the rest of the connections.

To eliminate the possibility of spikes or "back emf," a 1N4007 diode is soldered across the coil contacts of each relay. In addition, 0.01-µF capacitors across the diodes will reduce the possibility of stray RF causing problems with the relay operation.

Since the cable run from the shack to the tower can be quite long, consideration has to be given to the voltage drop that may occur. The relays require 12 V dc. The prototype used a 12 V dc regulator in the relay box, fed with 18 V dc (at 2 A) from the control box. If the cable run is not that long, however, you could just use a 12-V supply and skip the regulator.

One of the relays is used for lightning protection. When not in use, the relay grounds the line coming in from the shack. When the control box is activated, it applies power to this relay, thus removing the ground on the station feed line. All the antenna lines are grounded through the normally closed relay contacts. They remain grounded until the relay receives power from the control box.

## CONTROL BOX

This is the heart of the system. The 18 V dc power supply for the relays is located in this box, in addition to the Yaesu and ICOM decoder circuits and the relay-control circuitry. All connections to the relay box are made via an 8-position terminal barrier strip mounted on the back of the control box.

The front of the box has LEDs that indicate the selected antenna. A rotary switch can be used for manual antenna selection. The power switch and fuse are also located on the front panel.

The wiring schemes on the Yaesu and ICOM ACC sockets are so different that the unit shown in the photos has a 5-pin DIN connector for each rig on the control box. Since there is only one set of LEDs, use an 8-pin DIP header to select the appropriate control circuit for each radio. See Figure 26B. The unit is built with point-to-point wiring on project boards.

### ICOM Circuitry

This circuit originally appeared in April 1993 *QST* and is modified slightly for this application. The original circuit allowed for switching between seven antennas (from 160 to 10 meters). The Band Data signal from the ICOM radios goes to a string of LM339 comparators. Resistors R9 through R15 divide the 8-V reference signal from the rig to provide midpoint references between the band signal levels. The LM339 comparators decide which band the radio is on. A single comparator selects the 1.8 or 10 MHz band because those bands are at opposite ends of the range. The other bands each use two comparators. One determines if the band signal is above the band level and the other determines if it is below the band level. If the signal is between those two levels, the appropriate LED and relay-selection transistor switch is turned on.

The ICOM circuit allows for manual antenna selection. The 8-V reference is normally taken directly from the ICOM ACC socket. If this circuit is to be used with other equipment, then a regulated 8-V source should be provided.

### Yaesu Circuitry

The neat thing about Yaesu band data is that it's in a binary format. This means you can use a simple BCD decoder for band switching. The BCD output ranges from 1 to 9. In essence, you can switch among 9 antennas (or bands). Since the relay box switches just six antennas, steering diodes (D1 through D4 in Figure 24) allow the use of one antenna connection for multiple bands. One antenna connection is used for 17 and 15 meters, and another connection for 12 and 10 meters because the ICOM band data combines those bands. There is no control line or relay for a 30-meter antenna with this version of the project.

RFI has been reported to be caused by the CD4028 decoder IC (U5). Should this be the case for you, be sure the 7805 regulator is not oscillating and has the required bypass capacitors at the input and output. If the 7805 output is clean, add 0.01 µF, 50 V ceramic bypass capacitors to all pins of the CD4028 (except pin 8, the ground pin).

### DIP Sockets and Header

A project board holds the DIP sockets along with the relay keying transistors. This board is shown as the top layer in Figure 26B. The

Yaesu socket has 1-kΩ resistors wired in series with each input pin. The other header connects directly to the ICOM circuitry.

The DIP header is used to switch the keying transistors between the ICOM and Yaesu circuitry. The LEDs are used to indicate antenna number. Use stranded wire (for its flexibility) when connecting to the LEDs.

### Relay Keying Transistors

Both circuits use the same transistor-keying scheme, so you need only one set of transistors. Each transistor collector connects to the terminal barrier strip. The emitters are grounded, and the bases are wired in parallel to the two 16-pin DIP sockets. The band data turns on one of the transistors, effectively grounding that relay-control lead. Current flows through the selected relay coil, switching that relay to the normally open position and connecting the station feed line to the proper antenna.

### Power Supply

The power supply is used strictly for the relays. Other power requirements are taken from the rig used. There is room here for variations on the power supply theme; the parts used in this version were readily available.

# 6 A Raspberry-Pi Server/Client for Antenna Rotators

(This section is a summary of the Nov/Dec 2015 *AMSAT Journal* article "A Raspberry Pi Network Server/Client for Antenna Rotor," by Tom Doyle, W9KE. The complete article is available as a PDF document with the downloadable supplemental content. Changes by the authors of the *netServer*, *LVP Tracker*, or *K5FR VSP Manager* software may cause the functions described in this article to operate somewhat differently.)

With network connections becoming common in amateur equipment, this article describes a project that creates a network interface for an antenna rotator using the popular and inexpensive Raspberry Pi 2 single-board computer. It was originally designed to support satellite tracking with a Yaesu G-5500 rotator and LVB Tracker rotator control system but can be adapted to other uses and equipment. In addition, the Raspberry Pi can control commonly available relay boards with up to four relays for antenna polarity, power switching, and other on/off functions. The net server system is shown in **Figure 27**. The system block diagram is shown in **Figure 28**.

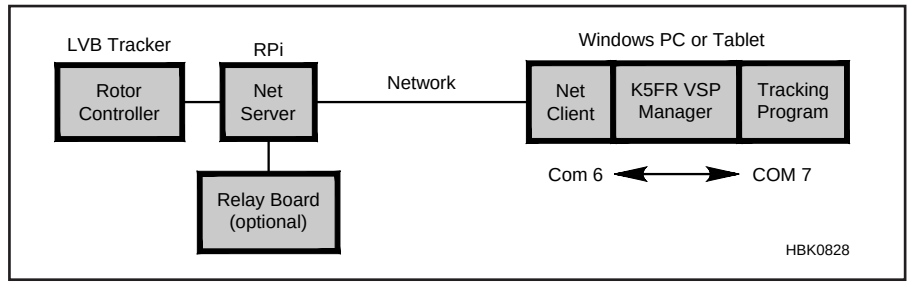

**Figure 28 — The block diagram showing how to use the Net Server/Client to control an azimuth/elevation control rotator.**

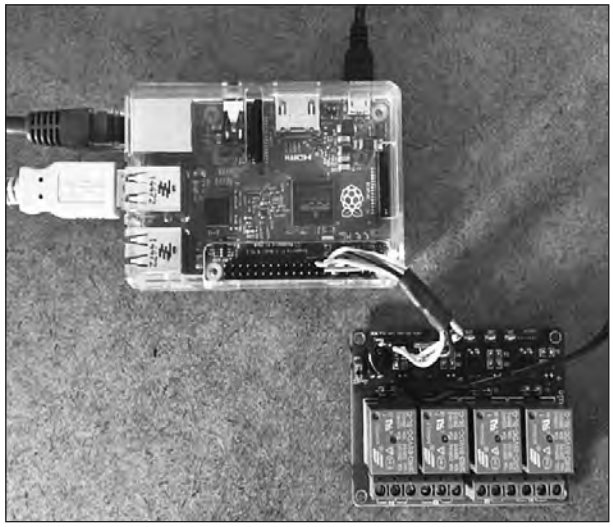

**Figure 27 — A photo of the Rasberry Pi 2 system showing the four primary connections: power, Ethernet, USB, and relays.**

### THE NET SERVER

A net server is a device used to create a network connection to a non-networked piece of equipment, in this case an antenna rotator controller. A net server can be especially useful when operating portable or from a remote location. The basic connections to the Raspberry Pi 2 (Raspi2) are shown in Figure 27: power, the RJ-45 Ethernet port, a USB connection to the LVB tracker board, and a five-wire connection to a relay control board. The USB and relay control board connections are optional, depending on station needs. The Model B version of the Raspberry Pi 2 running the default operating system, *raspian wheezy* was used for this project. Other models with equivalent resources may also be used.

Initial setup of the *Net Server* software (see the full article with the downloadable supplemental content) requires a keyboard, mouse and monitor be connected to the Raspi2. After the initial setup, it may be operated using a remote desktop connection. Since the Raspi2

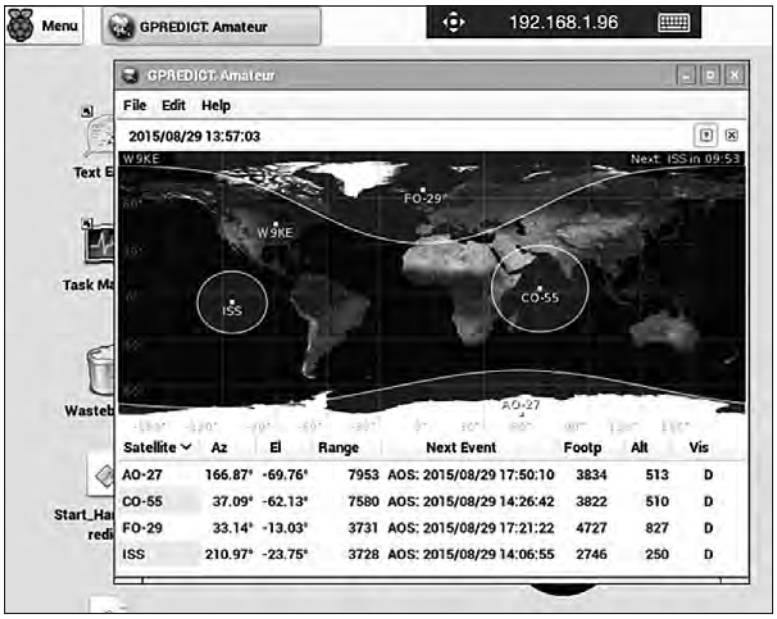

**Figure 29 — A screen shot of an iPad running both a remote access program (*Microsoft Remote Desktop*) connected to the Net Server/Client system and a satellite tracking program (*GPredict*).**

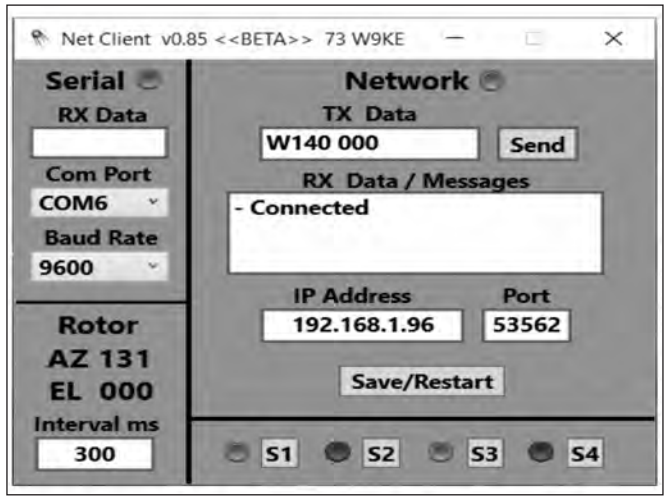

**Figure 30 — The *Net Client* software connected to an LVP Tracker, showing the control interface for the LVP Tracker and serial communications configuration.**

uses a multitasking operating system, it can run the *Net Server* program and another server program to allow access from a remote device at the same time. A Raspi operated without a local display, keyboard, or mouse is often referred to as "headless." (Complete setup and configuration instructions are included with the full article in the downloadable supplemental content.)

**Figure 29** shows a screen shot of an iPad running *Microsoft Remote Desktop* connected to *Net Server*. The Raspi2 is also running *GPredict* satellite tracking software. Access can also be obtained from a PC using *Remote Desktop Connection*. After the remote connection has been established, the Raspi2 can be operated from the remote device as if a keyboard, mouse, and monitor were connected directly to it. This helps reduce clutter in the shack and also reduces the cost of the system. It is also a very important advantage when operating portable.

If an LVB Tracker is connected to the Raspi2, the current azimuth (AZ) and elevation (EL) for the rotator are shown in the lower left part of the window in the section labeled "Rotor." (See **Figure 30**.) This value is updated at an interval shown in the "Interval ms" box.

The group of four buttons and indicators in the bottom right of the window (S1 – S4) control four relays if a suitable relay board is attached. After clicking on the S1 button, a message will be sent to the Raspi2 running *Net Server*, instructing it to turn on relay 1. When this has been done, *Net Server* will send back a message indicating that relay 1 is activated and the indicator to the left of the S1 button will turn from red to green. The indicator button will not turn green immediately, only after a confirming "relay on" message is received. The indicator will not change at all if there is not a network connection to a working *Net Server* system. The system waits to see if the message was received. (The system cannot tell whether a relay board is installed, however.)

To move the rotator, enter a valid LVB Tracker/Yaesu GS-232 move command, then click the Send button and the rotator should move to the new position. The position information is shown in the Rotor portion of the display and will track the move with updates at an interval specified in the "Interval ms" text box.

If changes are made to the values in the window other than the "TX Data" text box, the Save/Restart button will turn yellow as a reminder to save the changes. By clicking on the Save/Restart button, the values will be saved and the program will automatically restart. When deciding what to hook up to the relays, take into account that the relays will all be turned off whenever the Net Server starts up.

The Serial section of the screen shows the controls used to configure the serial port that connect to external programs with a serial interface, such as the LVP Tracker software. *K5FR VSP Manager* software is used to set up a pair of virtual serial ports. One of the ports is connected to the external program such as an LVP Tracker and the other to *Net Client* using the check boxes in the Serial area of the *Net Client* window.

When the serial port connection is made, the indicator button to the right of the word Serial will turn green. In Figure 30, *Net Client* is connected to virtual port COM6 at 9600 baud and COM7 is connected to the tracking program. This allows the software to send messages to the rotator.

# 7 Audible Antenna Bridge

The audible antenna bridge (AAB) shown in **Figure 31** was designed by Rod Kreuter, WA3ENK. This project would help a visually impaired ham, but sighted hams will also find it very useful. (For example, tuning a mobile screwdriver antenna while you're driving.) The AAB is rugged and easy to use, both in the harsh light of day and in the dark of night. It's also inexpensive to build, and a kit is available.[1]

An absorptive type of SWR meter, the AAB is used to indicate how close the match is between your transmitter and your antenna. Its output is a tone whose pitch is proportional to SWR. It also sends the SWR value in Morse code.

Unlike most SWR meters on the market, this one actually absorbs power from your transmitter while you're tuning, helping to protect your transmitter during tune-up. Many transmitters have SWR foldback capability and will decrease the output power if the antenna match is poor, but some do not.

By absorbing power in the AAB, no matter what you do at the antenna port, the transmitter never sees an SWR greater than 2:1. The trade-off is that 75% of your transmitter power ends up as heat in the bridge, so you need to switch out the AAB after you have tuned your antenna.

**Figure 31 — Front view of the audible antenna bridge.**

## THEORY OF OPERATION

The AAB works on a principle taken right from the *ARRL Antenna Book*. The bridge consists of four impedances, or arms. See **Figure 32**. If three of the arms are 50 Ω resistors and the fourth is an antenna (or an antenna and tuner combination), then the bridge will be balanced when the antenna port is also 50 Ω. Diodes D1 and D2 sample the forward and reverse voltages, respectively. A peripheral interface controller (PIC) with a 10 bit analog to digital converter (A/D) digitizes these voltages and calculates the SWR.

The SWR is used to control a hardware pulse width modulator that produces the output tone. It's also used by the Morse code routine to send the actual value of SWR, at 15 WPM with 5 WPM spacing.

The power that the AAB can handle during tune-up is a function of the resistors used in the three reference arms of the bridge. The 30 W noninductive resistors, R1-R3, are made by a number of companies but are not cheap. The bridge resistors must be noninductive. Don't use wire wound resistors!

Antenna tuning should be done with minimal power, and the AAB will work down to about 1 W. The 30 W resistors will handle tune-ups with about 60 W or perhaps 100 W for a short time. If you always remember to turn down your transmitter power, and you tune up quickly, the bridge resistors could be perhaps 5 W for normal rigs and 1 W for QRP rigs.

## BUILDING THE AAB

A PC board is a nice way to build the AAB, but you could easily construct such a simple circuit using ugly construction. Keep the wires short in the RF section. See **Figure 33**.

Use a heat sink for the noninductive resistors. Like many power devices, the power rating depends on getting the heat out! These resistors get really hot running at 10 or 20 W. See **Figure 34**. Use a big heat sink with heat sink compound, give yourself plenty of room in the cabinet and drill some holes to let the heat escape.

Switch S1 chooses TUNE/OPERATE and S2, the INQUIRE button, is used to report on various conditions, such as the SWR value in Morse code. You can eliminate the TUNE/OPERATE switch, but remember to remove the AAB from your feed line after tuning up.

To use the AAB in a QRP station, you may want to reduce resistors R4 and R5. They are sized so that a 25 W transmitter will not saturate the analog to digital converter (ADC) on the PIC when using fresh batteries (more on this later). A good value for a 5 W transmitter would be about 20 kΩ. So long as the voltages at pin 12 and pin 13 of U1 are below the battery voltage, the system will work fine.

## POWERING THE AAB

To save power the AAB uses a sleep mode. If you haven't pushed the INQUIRE button for about 5 minutes, the AAB will go to sleep after sending the letter N for "night night." During sleep the current draw is about 2 µA. Pushing the switch while it's sleeping will wake up the AAB and it will send the letter U ("up").

The first four prototypes used four AAA batteries and a low-dropout 4.7 V regulator. This made for a nice stiff supply and very good battery life, with only one problem. Even though the PIC uses less than 2 µA during sleep, the regulator uses 500 µA. Battery data says that alkaline AA batteries will last 6 months at this level and AAA batteries about half that long. Consider adding an ON/OFF switch if you go this route.

The other option is to use batteries without a regulator. Normally you couldn't get away with this without providing a separate voltage reference for the ADC in the PIC. In this case it doesn't matter as much because SWR is a ratio of two voltages.

What does matter is the battery voltage with respect to the voltage produced by the RF signal. Diodes D1 and D2 rectify the RF and produce a dc voltage proportional to RF power. This voltage is divided by resistors R4, R6 and R5, R7. The voltage at the ADC inputs of the PIC, pins 12 and 13, must be less than the power supply voltage. With a regulated supply this isn't much of a problem, and if you're careful it can also work with unregulated batteries.

Microchip recommends that these parts be run on 2.5 to 5.5 V if you need the 10 bit ADC to be accurate. Many battery combinations will provide this, but consider lithium batteries instead of alkaline. The voltage from an alkaline battery begins to fall very early in its life and continues at a downward slope until it is exhausted. A lithium battery, on the other hand, provides a nearly constant voltage throughout its useful life. A 3.6 V AA size lithium should last a few years, but with the lower output voltage you may want to reduce R4 and R5. The final prototype used three AAA lithium batteries (each about 1.7 V when new), with no regulator or ON/OFF switch, which should last at least two years.

U1's ADC converter will saturate at some level. With new batteries, let's say this level is

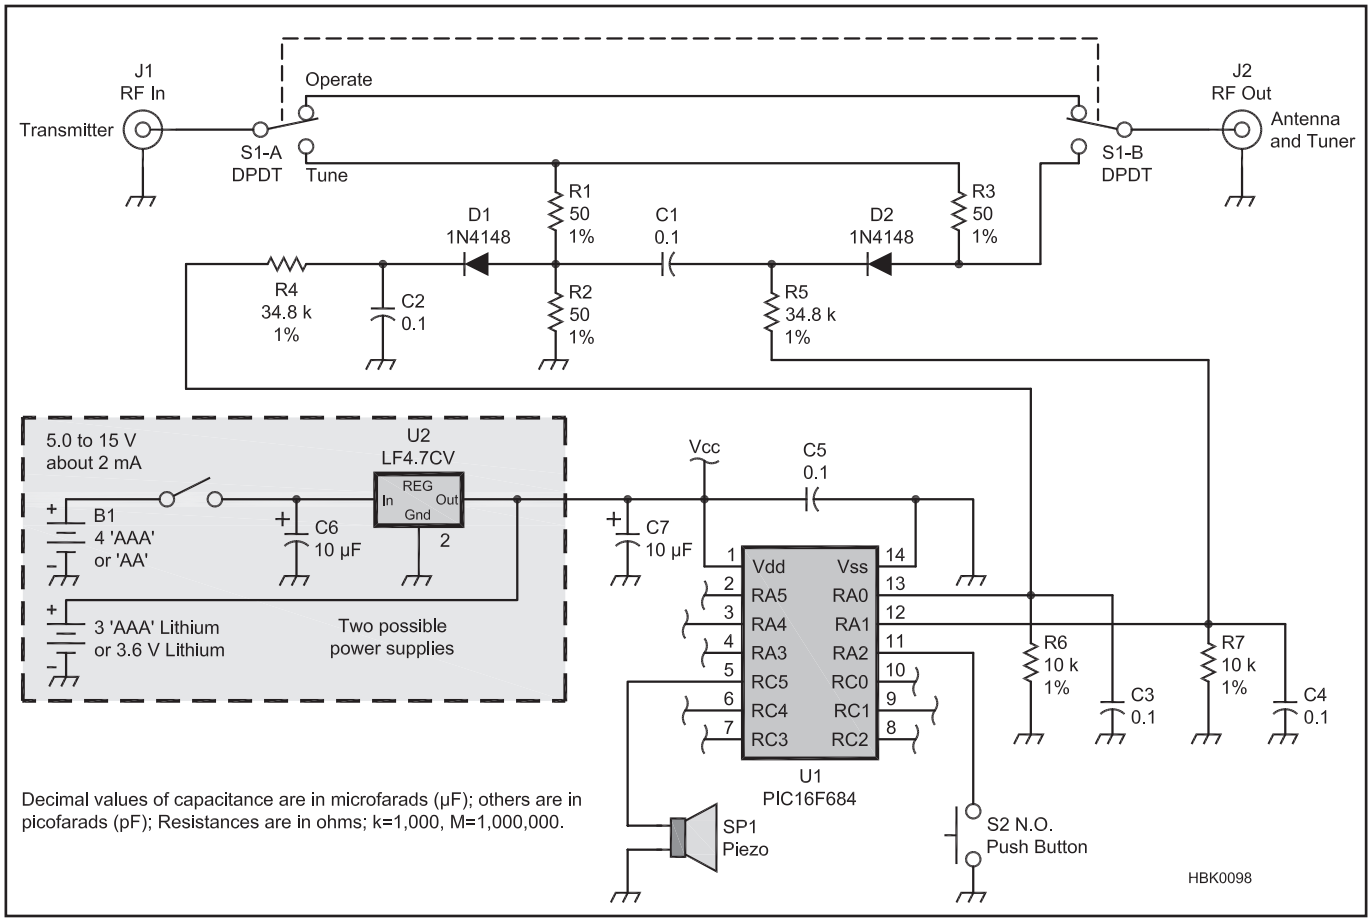

**Figure 32 — Schematic and parts list of the AAB.**

**SP1 — Piezoelectric buzzer EFB-RD24C411 (Digi-Key P9924-ND).**
**U1 — PIC16F684 (Digi-Key PIC16F684-1/P-ND). Must be programmed before use. See Note 1.**
**U2 — LF4.7CV regulator (Mouser 511-LF47CV).**

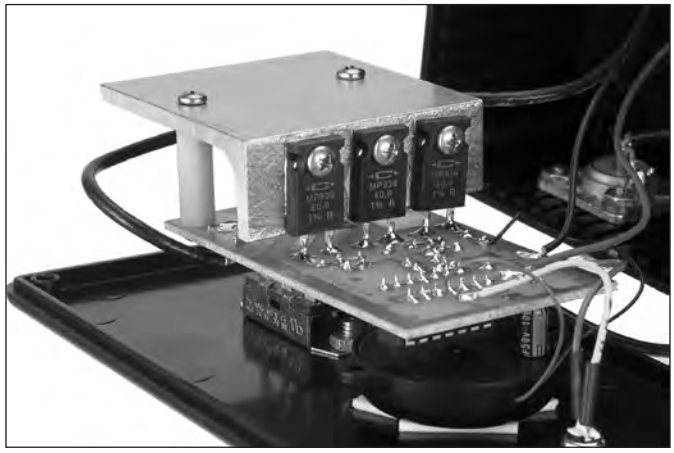

**Figure 33 — Close-up view of three CaddockTO-220 style bridge resistors mounted on the heat sink.**

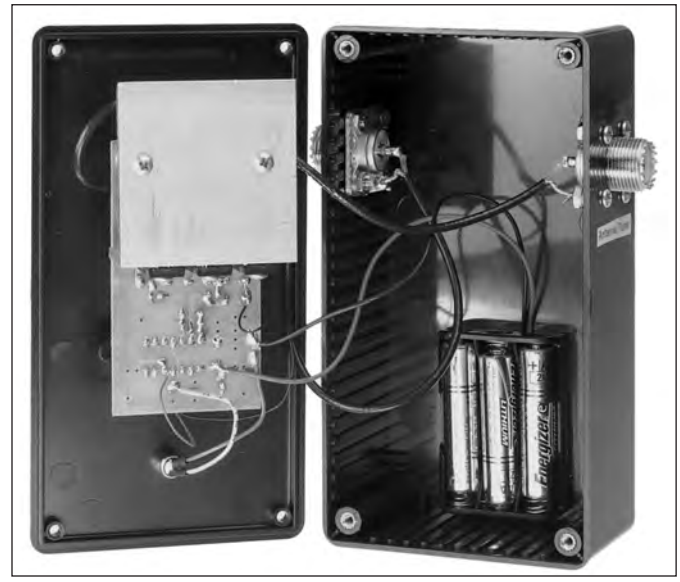

**Figure 34 — Interior view of the AAB, showing the battery pack at the bottom of the enclosure.**

25 W when the power supply is 4.5 V. When the power supply has fallen to 3.5 V, the RF level that will saturate the converter will be 15 W. So if you find that the output of your rig, which used to be fine, is now saturating the ADC, it's time to change batteries.

### USING THE AAB

Connect your transmitter to the INPUT and your antenna/tuner to the OUTPUT. Turn your transmit power down to 5 or 10 W and put S1 in the TUNE position. Wake the AAB up by pushing the INQUIRE button. Key your transmitter in a mode with some carrier power. The AAB should start to produce a steady tone. Adjust your tuner or antenna for the lowest tone pitch. Press the INQUIRE button for the numeric SWR value.

When the AAB is operating normally, it produces a tone proportional to SWR. The tone ranges from 250 Hz at an SWR of 1.0:1, rising to 4450 Hz at an SWR of about 15:1. Errors can occur and at times the AAB can't make a measurement. If an error occurs, either a high pitched tone or no tone is produced. Pushing the INQUIRE button will give you more information. Five different conditions can occur:

*Normal operation*. A tone proportional to SWR is produced. Press INQUIRE and a two digit SWR value is sent, separated by the letter R (Morse for the decimal point character).

*Error 1*. The forward power is too low for a reliable measurement. No tone is produced. INQUIRE button sends letter L (low).

*Error 2*. Forward power is too high (almost saturating the ADC). A pulsing tone proportional to SWR is produced. However, if the ADC is saturated this value might be meaningless. INQUIRE button sends letter S (saturated).

*Error 3*. SWR is greater than 9.9:1. A tone proportional to SWR is produced. INQUIRE button sends letter H (high).

*Error 4*. The reverse voltage is greater than the forward voltage. Two things can cause this error. You might be near a high power transmitter, or you connected the transmitter to the output port. No tone is produced. INQUIRE button sends letter F (fault).

The PIC used in this design could be used in a more standard SWR meter, such as those with a transformer type sensor. As long as the meter produces a forward and reverse voltage that you can scale to be from 0 to 3 up to 5 V (depending on your power supply choice), it will work just fine. However, the driving impedance of the voltage must be 10 kΩ or less.

The author thanks the Ham Radio Committee of the National Federation of the Blind for inspiration, and Tom Fowle, WA6IVG, and Bill Gerrey, WA6NPC, of the Smith-Kettlewell Research Institute for testing prototypes.

[1]A kit of parts including a printed circuit board is available from Q-Sat, 319 McBath St, State College, PA 16801. The price is currently $30, postpaid. PC boards are available for $7 postpaid and a programmed PIC is available for $6 postpaid. Source code for an unprogrammed PIC is available on the ARRL Web site. Go to **www.arrl.org/qst-in-depth** and look for Kreuter0607.zip in the 2007 section.

# 8 A Trio of Transceiver/Computer Interfaces

Virtually all modern Amateur Radio transceivers (and many general-coverage receivers) have provisions for external computer control. Most hams take advantage of this feature using software specifically developed for control, or primarily intended for some other purpose (such as contest logging), with rig control as a secondary function.

Unfortunately, the serial port on most radios cannot be directly connected to the serial port on most computers. The problem is that most radios use TTL signal levels while most computers use RS-232-D.

The interfaces described here simply convert the TTL levels used by the radio to the RS-232-D levels used by the computer, and vice versa. Interfaces of this type are often referred to as level shifters. Two basic designs, one having a couple of variations, cover the popular brands of radios. This article, by Wally Blackburn, AA8DX, first appeared in February 1993 *QST*.

### TYPE ONE: ICOM CI-V

The simplest interface is the one used for the ICOM CI-V system. This interface works with newer ICOM and Ten-Tec rigs. **Fig**ure **35** shows the two-wire bus system used in these radios.

This arrangement uses a CSMA/CD (carrier-sense multiple access/collision detect) bus. This refers to a bus that a number of stations share to transmit and receive data. In effect, the bus is a single wire and common ground that interconnect a number of radios and computers.

The single wire is used for transmitting and receiving data. Each device has its own unique digital address. Information is transferred on the bus in the form of packets that include the data and the address of the intended receiving device.

The schematic for the ICOM/Ten-Tec interface is shown in **Figure 36**. It is also the Yaesu interface. The only difference is that the transmit data (TxD) and receive data (RxD) are jumpered together for the ICOM/Ten-Tec version.

The signal lines are active-high TTL. This means that a logical one is represented by a binary one (+5 V). To shift this to RS-232-D it must converted to –12 V while a binary zero (0 V) must be converted to +12 V. In the other direction, the opposites are needed: –12 V to

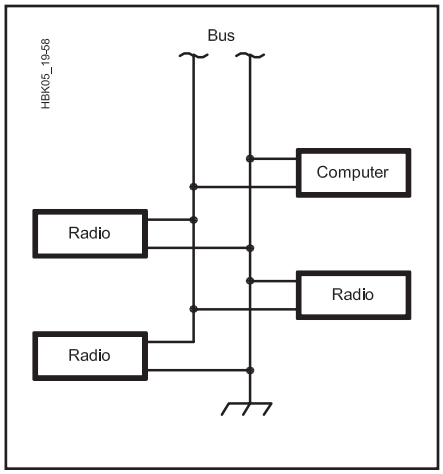

**Figure 35 — The basic two-wire bus system that ICOM and newer Ten-Tec radios share among several radios and computers. In its simplest form, the bus would include only one radio and one computer.**

+5 V and +12 V to 0 V.

U1 is used as a buffer to meet the interface specifications of the radio's circuitry and provide some isolation. U2 is a 5-V-powered RS-232-D transceiver chip that translates between TTL and RS-232-D levels. This chip uses charge pumps to obtain ±10 V from a single +5-V supply. This device is used in all three interfaces.

A DB25 female (DB25F) is typically used at the computer end. Refer to the discussion of RS-232-D earlier in the chapter for 9-pin connector information. The interface connects to the radio via a ⅛-inch phone plug. The sleeve is ground and the tip is the bus connection.

It is worth noting that the ICOM and Ten-Tec radios use identical basic command sets (although the Ten-Tec includes additional commands). Thus, driver software is compatible. The manufacturers are to be commended for working toward standardizing these interfaces somewhat. This allows Ten-Tec radios to be used with all popular software that supports the ICOM CI-V interface. When configuring the software, simply indicate that an ICOM radio (such as the IC-735) is connected.

### TYPE TWO: YAESU INTERFACE

The interface used for Yaesu rigs is identical to the one described for the ICOM/Ten-Tec, except that RxD and TxD are not jumpered together. Refer to Figure 36. This arrangement uses only the RxD and TxD lines; no flow control is used.

The FT-990 and FT-1000/FT-1000D use an emitter follower as the TTL output. If the input impedance of the interface is not low enough to pull the input below threshold with nothing connected, the FT-990/FT-1000 (and perhaps other radios) will not work reliably. This can be corrected by installing a 1.5 kΩ resistor from the serial out line to ground

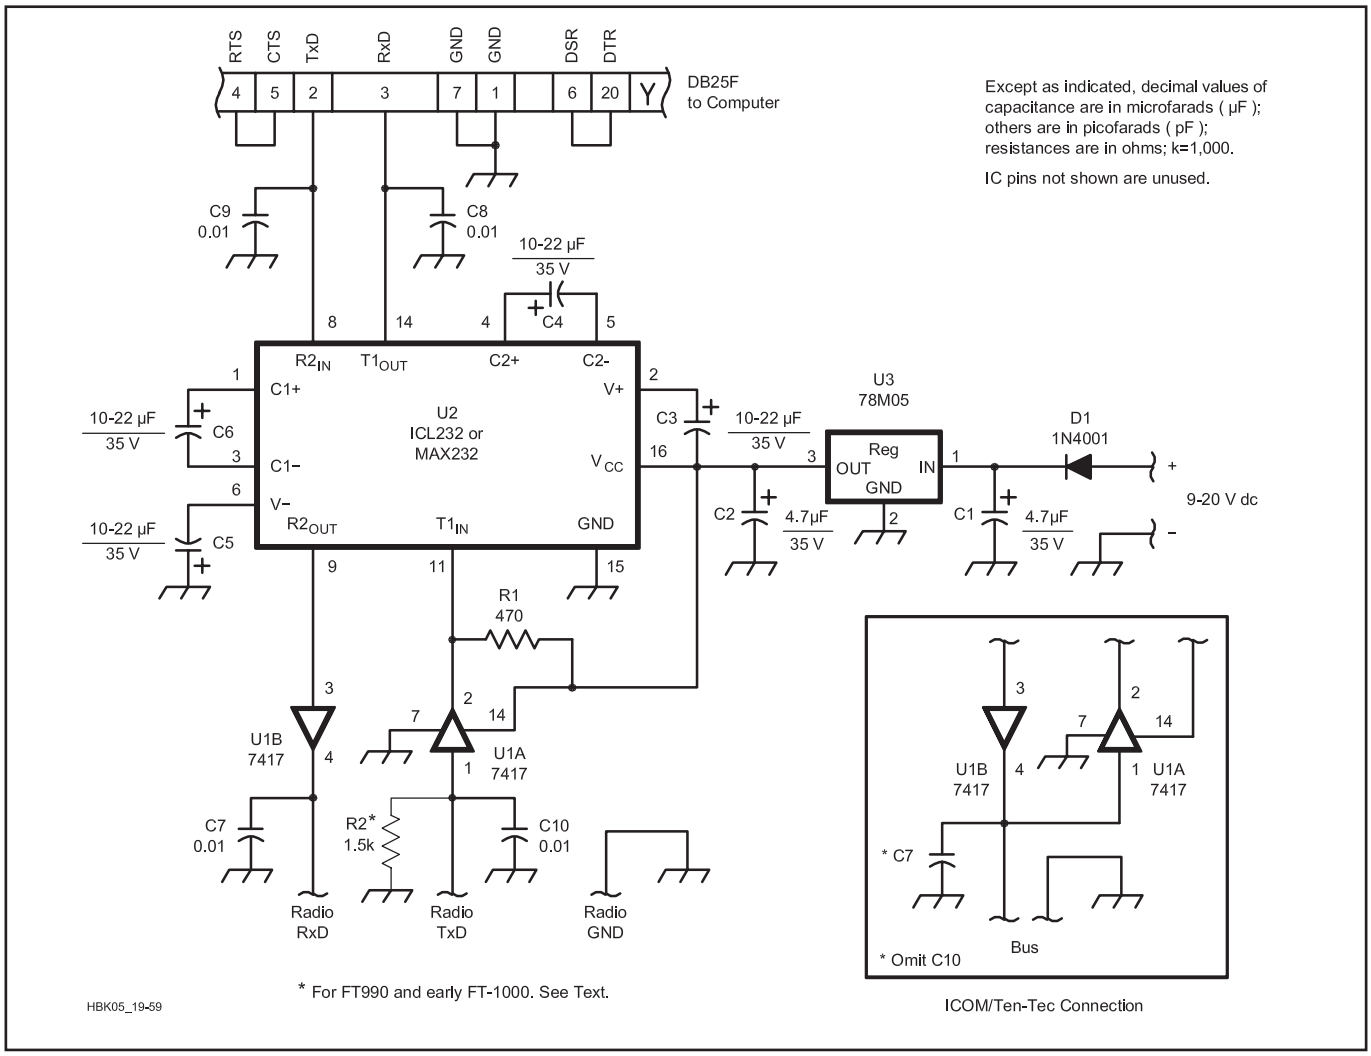

**Figure 36 — ICOM/Ten-Tec/Yaesu interface schematic. The insert shows the ICOM/Ten-Tec bus connection, which simply involves tying two pins together and eliminating a bypass capacitor.**

**C7-C10 — 0.01-µF ceramic disc.** **U1 — 7417 hex buffer/driver.** **U2 — Harris ICL232 or Maxim MAX232.**

(R2 on pin 1 of U1A in Figure 36.) Later FT-1000D units have a 1.5 kΩ pulldown resistor incorporated in the radio from the TxD line to ground and may work reliably without R2.

The same computer connector is used, but the radio connector varies with model. Refer to the manual for your particular rig to determine the connector type and pin arrangement.

### TYPE THREE: KENWOOD

The interface setup used with Kenwood radios is different in two ways from the previous two: Request-to-Send (RTS) and Clear-to-Send (CTS) handshaking is implemented and the polarity is reversed on the data lines. The signals used on the Kenwood system are active-low. This means that 0 V represents a logic one and +5 V represents a logic zero. This characteristic makes it easy to fully isolate the radio and the computer since a signal line only has to be grounded to assert it. Optoisolators can be used to simply switch the line to ground.

The schematic in **Figure 37** shows the Kenwood interface circuit. Note the different grounds for the computer and the radio. This, in conjunction with a separate power supply for the interface, provides excellent isolation.

The radio connector is a 6-pin DIN plug. The manual for the rig details this connector and the pin assignments.

Some of the earlier Kenwood radios require additional parts before their serial connection can be used. The TS-440S and R-5000 require installation of a chipset and some others, such as the TS-940S require an internal circuit board.

### CONSTRUCTION AND TESTING

The interfaces can be built using a PC board, breadboarding, or point-to-point wiring. PC boards and MAX232 ICs are available from FAR Circuits. The PC board template is available with the downloadable supplemental content.

It is a good idea to enclose the interface in a metal case and ground it well. Use of a separate power supply is also a good idea. You may be tempted to take 13.8 V from your radio — and it works well in many cases: but you sacrifice some isolation and may have noise problems. Since these interfaces draw only 10 to 20 mA, a wall transformer is an easy option.

The interface can be tested using the data in **Tables 6, 7** and **8**. Remember, all you are doing is shifting voltage levels. You will need a 5-V supply, a 9-V battery and a voltmeter. Simply supply the voltages as described in the corresponding table for your interface and check for the correct

| +5 V to Radio TxD | –8 to –12 V at PC-3 |
| +9 V to PC-2 | 0 V at Radio RxD |
| –9 V to PC-2 | +5 V at Radio RxD |

voltage on the other side. When an input of –9 V is called for, simply connect the positive terminal of the battery to ground.

During normal operation, the input signals to the radio float to 5 V because of pullup resistors inside the radio. These include RxD on the Yaesu interface, the bus on the ICOM/Ten-Tec version, and RxD and CTS on the Kenwood interface. To simulate this during testing, these lines must be tied to a 5-V supply through 1-kΩ resistors. Connecting these to the supply without current-limiting resistors will damage the interface circuitry. R5 and R6 in the Kenwood schematic illustrate this. They are not shown (but are still needed) in the ICOM/Ten-Tec/Yaesu schematic. Also, be sure to note the separate grounds on the Kenwood interface during testing.

Another subject worth discussing is the radio's communication configuration. The serial ports of both the radio and the computer must be set to the same baud rate, parity, and number of start and stop bits. Check your radio's documentation and configure your software and the radio to have identical communications settings.

# 9 A Simple Serial Interface

A number of possibilities exist for building an RS-232-to-TTL interface level converter to connect a transceiver to a computer serial port. The interface described here by Dale Botkin, NØXAS, is extremely simple, requiring only a few common parts.

Most published serial interface circuits fall into one of the following categories:

- Single chip, MAX232 type. These are relatively expensive, require several capacitors, take up lots of board space and usually require ordering parts.
- Single chip, MAX233 type. This version doesn't need capacitors. Otherwise it shares most of the characteristics of the MAX232 type device, but is even more expensive.
- Transistors. Usually transistor designs use a mix of NPN and PNP devices, four to eight or more resistors, and usually capacitors and diodes. This is just too many parts!
- Other methods. Some designs use series resistors, or TTL logic inverters with resistors. The idea is that the voltages may be out of specification for the chip, but if the current is low enough it won't damage the device. This is not always safe for the TTL/CMOS device. With just a series resistor the serial data doesn't get inverted, so it requires the use of a software USART. It can work, but it's far from ideal.

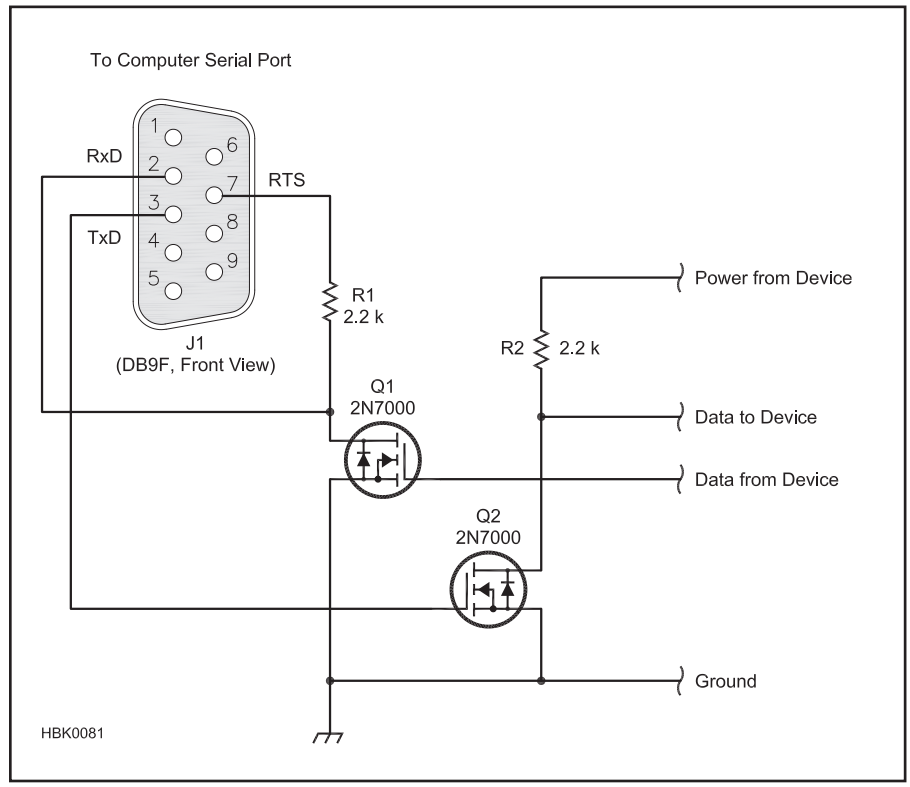

**Figure 38 — Schematic for the simple serial interface.**

**J1 — DB9F or connector to fit device serial port. Note that pin assignments for RxD, TxD and RTS are different on DB25 connectors.**

**Q1, Q2 — Small signal MOSFET, 2N7000 or equiv.**

## A SIMPLER APPROACH

The EIA-232 specification specifies a

signal level between ±3 V and ±12 V for data. The author looked at data sheets for devices ranging from the decades-old 1489 line receiver to the latest single-chip solutions. Not a single device found actually required a negative input voltage! In fact, the equivalent schematic shown for the old parts clearly shows a diode that holds the input to the first inverter stage at or near ground when a negative voltage is applied. The data sheets show that a reasonable TTL-level input will drive these devices perfectly well.

Relieved of the burden of exactly replicating the PC-side serial port voltages, the interface shown in **Figure 38** is designed for minimum parts count and low cost — under $1.

Why use MOSFETs for Q1 and Q2? In switching applications such as this, there are several advantages to using small signal MOSFETs over the usual bipolar choices like the 2N2222 or 2N3904. First, they need no base current limiting resistors — the MOSFET is a voltage operated device, and the gate is isolated from the source and drain. The gate on a 2N7000 is rated for ±20 V, so you don't need a clamping diode to prevent negative voltages from reaching the gate. They can also be had just as cheaply as their common bipolar cousins. (If sourcing 2N7000s is a challenge in Europe, the BS170 is basically identical except for the pins being reversed.) Now all that is needed is a drain limiting resistor, since the gate current is as close to zero as we are likely to care about.

Q1 gets its input from the TTL-level device. Q1 and R1 form a simple inverter circuit, with the inverted output going to pin 2 (RxD) of the serial connector. The pull-up voltage for RxD comes from pin 7 (RTS) of the serial connector, so the voltage will be correct for whatever device is connected — be it a PC or whatever else you have. Q2 and R2 are another inverter, driven by TxD from pin 3 of the serial connector. The pull-up voltage for R2 should be supplied by the low-voltage device — your radio or microcontroller project.

There you go. Two cheap little MOSFETs, two resistors. The 2.2 kΩ, ¼ W resistors seem to work with every serial port tried so far. The author has sold several hundred kits using this exact circuit for the serial interface without issues from any users. It's been tested with laptops, desktops, USB-to serial-converters, a serial LCD display, and even a Palm-III with an RS-232 serial cable. It's also been used with very slight modifications in computer interfaces for VX-7R and FT-817 transceivers. It's simple, cheap and works great — what more could you ask?

# 10 USB Interfaces For Your Ham Gear

Serial ports have disappeared from most new computers. The once-ubiquitous serial port, along with other interfaces that were once a basic part of every computer system, has largely been replaced by Universal Serial Bus (USB) ports. This presents problems to the amateur community because serial ports have been and continue to be the means by which we connect radios to computers for control, programming, backing up stored memory settings, contest logging and other applications. Radios equipped with USB ports are rare indeed, and many of the optional computer interface products sold by ham manufacturers are serial-only. The project described here by Dale Botkin, NØXAS, offers a solution.

## THE UNIVERSAL SERIAL BUS

So what is USB, and how can it be used in the ham shack? The USB standard came about during the early 1990s as a replacement for the often inconvenient and frustrating array of serial, parallel, keyboard, mouse and various other interfaces commonly used in personal computer systems. The idea is to use a single interface that can handle multiple devices sending and receiving different types of data, at different rates, over a common bus. In practice, it works quite well because of the very well defined industry specification for signal levels, data formats, software drivers and so forth.

At least two and sometimes as many as six or more USB ports are now found as standard equipment on nearly all new computer systems. Support for USB ports and generic USB devices is built into most operating systems including *Windows*, *Linux*, *Solaris*, *Mac OS* and *BSD* to name a few. USB use has spread beyond computers, and the standard USB "B" or the tiny 4-conductor "Mini B" connectors are now found on all manner of electronic devices including cameras, cell phones, PDAs, TVs, CD and DVD recorders, external data storage drives and even digital picture frames. USB is indeed becoming *universal*, as its name implies — everywhere, it seems, except for Amateur Radio gear!

The EIA-232 serial interface specification we have used for decades is just that — an electrical interface specification that defines voltage levels used for signaling. The asynchronous serial format most commonly used with serial ports defines how data is sent over whatever interface is being used. Any two devices using the same protocol and format can talk to each other, whether they are both computers, both peripheral devices (like printers, terminals or TNCs) or any combination. All that is required is the proper cable and the selection of matching parameters (speed, data bits, handshaking) on each end of the connection.

This is not the case with USB devices. USB uses a tiered-star architecture, with well defined roles for the host controller (your computer) and devices. Devices cannot communicate directly with each other, only with a host.

See **Figure 39**. At the top of the stack is the *host controller device* (HCD), usually your computer, which controls all communication within the USB network. The computer may have several host controllers, each with one or more ports. The host controller discovers, identifies and talks to up to 127 devices using a complex protocol. No device can communicate directly with another device; all communication is initiated and controlled by the host controller. As a result, you cannot simply connect two USB devices together and expect them to communicate. (Some USB printers will talk directly to digital cameras because the printer also has a host controller built in.)

As you have probably already figured out, moving from serial to USB is not a simple

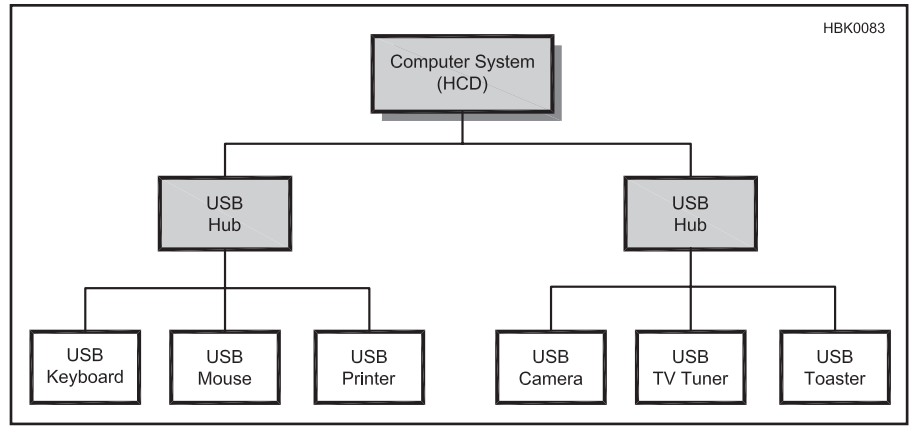

**Figure 39 — Typical USB architecture.**

matter of converting voltage levels or even data formats. USB devices all need some embedded "smarts," usually in the form of either a dedicated USB interface chip or a microcontroller using firmware to talk to the USB host. Where we could once use simple transistor circuits to adapt RS-232 serial to the TTL voltage levels used by many radios, we now must add the complete USB interface into the picture.

The USB specification is freely available and well documented, and there are books dealing with designing the software to use the interface. If you're starting from scratch it is a very daunting task to even understand exactly how USB works, let alone design and build your own USB-equipped device. If you're willing and dedicated enough, you can implement your own USB device using a fairly broad range of available microcontrollers. There are also dedicated function chips that implement a complete USB interface — or parts of it — in one or two devices.

Fortunately, several manufacturers have stepped up to make using USB relatively easy for the experimenter. One of the most commonly used solutions is from Future Technology Devices International (FTDI). FTDI manufactures a line of USB interface chips that plug into the Universal Serial Bus on one side and present a serial or parallel interface on the other side. The chips are quite versatile and are commonly used to add USB functionality to a wide range of devices ranging from cell phones to USB-to-serial cables. They are also available in several forms such as plug-in modules with a USB connector and the interface logic, all on a small PC board with pins that can be plugged into a standard IC socket.

## CONSTRUCTION

This project uses an FT232R series chip from FTDI to bridge the USB interface from your computer to a TTL-level serial interface that can be adapted to use with many different ham rigs. The chip has built-in logic to handle the USB interface, respond to queries and commands from the computer, and send and receive serial data. By using special drivers available from FTDI (and built into *Windows* and many other systems), it can appear to your programs as a standard serial COM port.

Once the conversion to serial data is done, all that remains is to adapt the signals to the particular interface used by your equipment. In many cases, this serial data can simply be connected directly to the rig using the appropriate connector. In others it may require some extra circuitry to accommodate various interface schemes used by manufacturers. The most common is an open-collector bus type interface, which is easily accommodated using a few inexpensive parts.

Construction of this project can be handled in a couple of different ways. The FT232R series chips are available from various suppliers at low cost. Unfortunately they are only available in SSOP and QFLP surface mount packages that can be difficult to work with unless you use a custom printed circuit board. (An additional letter is tacked onto the part number to identify the package. For example, the FT232RL uses a 28-pin SSOP package.) There are SSOP-to-through-hole adapter boards available, but they are relatively expensive and still require some fine soldering.

Fortunately FTDI also sells a solution in the form of the TTL-232R (**Figure 40**). It incorporates a USB "A" connector, an FT232RQ chip and the required power conditioning on a tiny PCB encapsulated in plastic, all about the size of a normal USB connector. A 6-ft long cable terminates in a 6-position inline header that provides ground, +5 V, and TTL level TxD, RxD, RTS and CTS signals.

You can connect these signals directly to your own microprocessor projects and have an "instant" USB connection. You can also build a variety of interface cables or boards for use with different radios. This arrangement is ideal for the experimenter and the person who might need several different interfaces for use with several different rigs — like many of us! The cost of the TTL-232R cable is quite reasonable, in fact lower than the cost of having a prototype PCB made to build your own equivalent device. Of course that option is still available to those who need more flexibility.

## USING USB IN THE SHACK

With the USB-to-serial conversion handled so easily, the only remaining task is to adapt the TTL-level serial interface of the FT232R to the interface used by your particular radio. In the case of some rigs, such as the Yaesu FT-817, Kenwood TM-G707A and many others, it's simply a matter of wiring up the right connector, as shown in **Figure 41**.

For communicating with individual ICOM and Ten-Tec rigs, one simple solution is to simply connect the transmit and receive data signals together and wire up a ⅛-inch stereo plug as shown in **Figure 42**. This will work with a single device connected, but lacks the open-collector drivers needed to be compatible with attaching multiple devices to the CI-V bus.

**Figure 40 — The FTDI TTL-232R cable simplifies construction.**

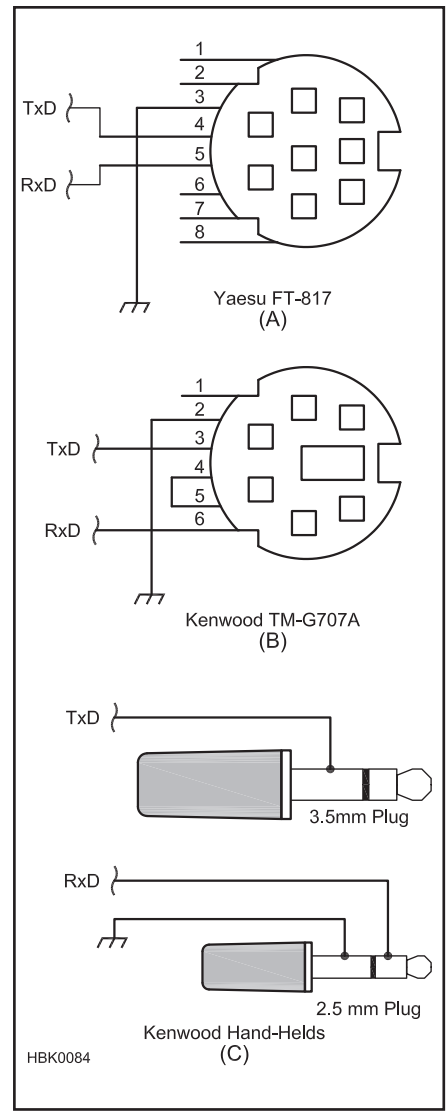

**Figure 41 — Using the FTDI USB-to-serial interface with some radios is as simple as wiring up a connector. Connections for the Yaesu FT-817 are shown at A, the Kenwood TM-G707A (PG-4 type) at B, and Kenwood hand-helds (PG-5 type) at C. Ground, RxD and TxD connections are made to the 6-pin connector on the TTL-232R cable.**

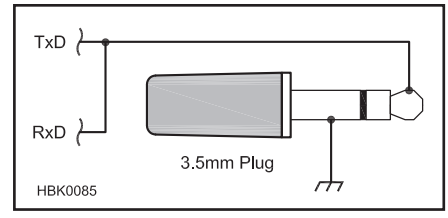

**Figure 42 — The transmit and receive data signals can be connected together for use with a single Ten-Tec or ICOM CI-V device.**

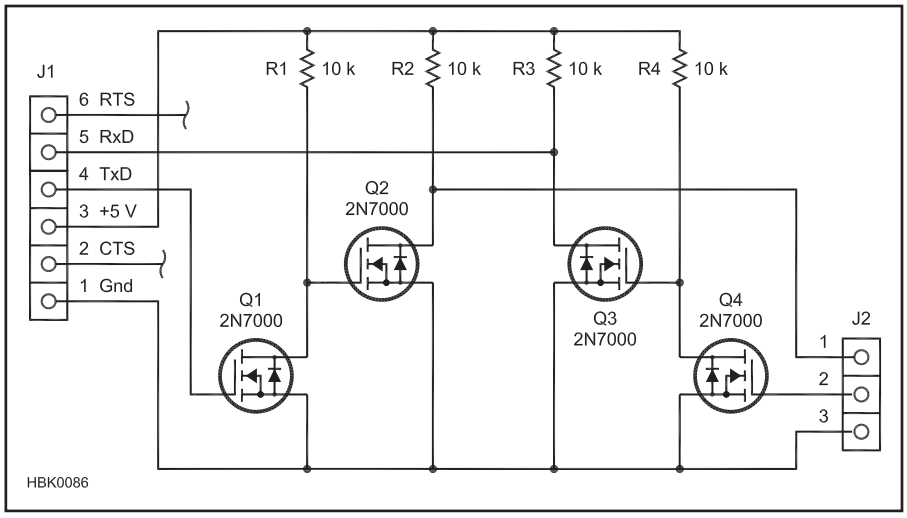

**Figure 43 — Schematic of the basic interface buffer board.**

**J1 — 6-pin, 0.1-in pitch header to match TTL-232R cable.**
**J2 — 3-pin header to match radio cable.**
**Q1-Q4 — Small-signal MOSFET, 2N7000, BS-170 or equiv.**
**R1-R4 — 10 kΩ, ¼ W.**

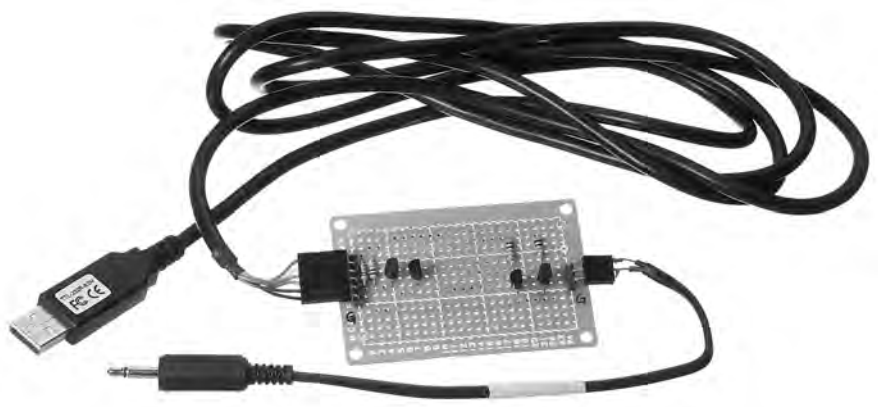

**Figure 44 — The completed buffer board. Adapter cables for various radios plug into the header on the right edge of the board.**

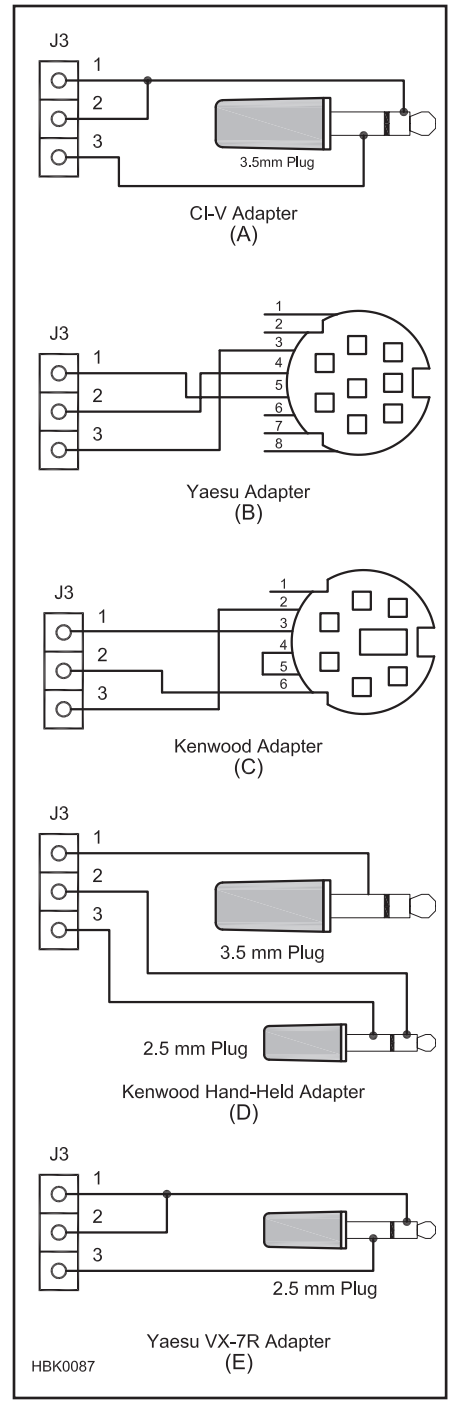

**Figure 45 — Adapters for using the buffer board with various radios. J3 matches the adapter used on the buffer board.**

## A LITTLE MORE VERSATILITY

Many hand-held transceivers use a single data line for both transmit and receive. This method is very similar to CI-V, but requires an open-collector or open-drain configuration for a single device. Some additional buffering is required to provide an interface to the rig.

**Figure 43** shows the design of the general-purpose buffer board for use with various radios. This circuit simply provides a noninverting, open-drain buffer for data in each direction. Adapters for various rigs can be plugged into J2 with no further changes needed. Use of MOSFETs instead of their bipolar counterparts simply reduces the parts count. No additional resistors are needed to limit base current, as you would need when using 2N2222 or similar transistors. Parts can be mounted on a small project board as shown in **Figure 44**.

This arrangement turns out to be extremely versatile and will work with CI-V, FT-817, Yaesu VX-series handhelds and the other rigs the author was able to test as well. All that is required is the proper adapter cable from the base interface board to the rig. Some examples are shown in **Figure 45**.

## ADDING PTT

Handling PTT is quite simple, and it can be done either with or without isolation as shown in **Figure 46**. For a non-isolated PTT line, we can simply drive the gate of a 2N7000 or similar MOSFET from the FT232RL's RTS output. If you prefer an optically isolated PTT output, all you need to add is one resistor and an optocoupler such as a 4N27 or PS-7142. Note that the TTL-232R provides a 100 Ω resistor in series with the RTS signal (the same is true for TxD), so a smaller value resistor (R1) can be used for the optocoupler's input than you would normally use.

While connecting the data lines directly to the rig is a suitable solution for many applications, some Kenwood HF rigs require a different approach. They require inverted TTL-level data, and may experience "hash" noise from the computer when not using an isolated interface. **Figure 47** shows an optically isolated method of connecting to a Kenwood rig such as the TS-850S. Note that this has not been tested but the design is similar to numerous examples of serial interfaces for the TS-850S and similar radios.

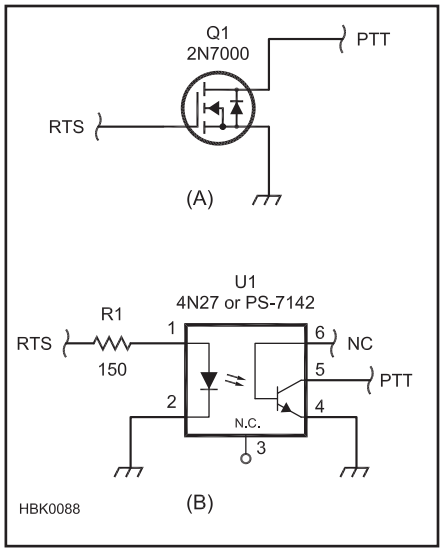

**Figure 46 — PTT can be added either without isolation (A) or with an optoisolator (B).**

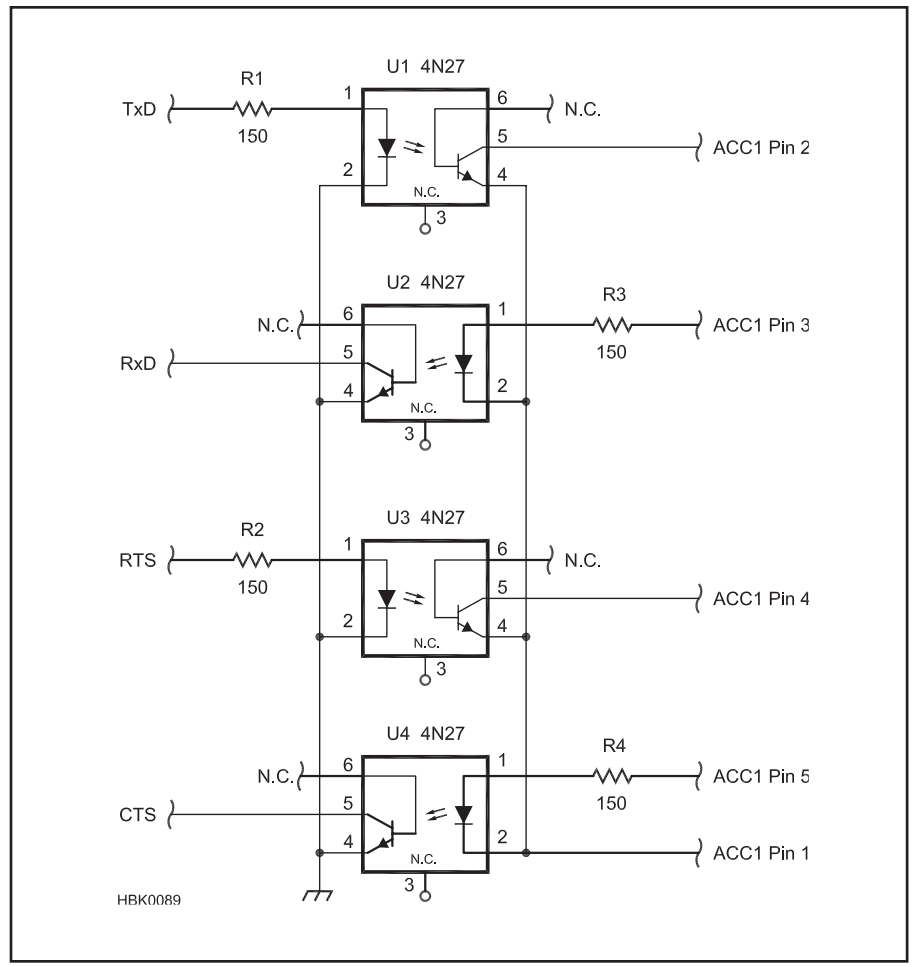

**Figure 47 — Isolated Kenwood interface for the TS-850S and similar HF transceivers requiring inverted TTL-level data and isolated lines.**

It's probably only a matter of time before we start seeing the tiny USB "Mini B" connector appear on new ham gear. It has become inexpensive and easy to add USB to pretty much any product, and as serial ports become more and more rare the manufacturers will eventually face overwhelming consumer demand to switch. In the meantime, you can do a little homebrewing and use your new, serial port free computer to talk to all of your ham gear for very little cost.

# 11 Keying and Tube Gear Interfaces

Switching and keying interfaces designed for today's solid-state, low-voltage equipment are not suited for direct connections to vacuum tube gear or other equipment that uses higher positive or negative voltages. This section presents a keying interface by NØXAS and two general-purpose interfaces that can be adapted to a variety of interface needs.

## 11.1 The Universal Keying Adapter

When Dale Botkin, NØXAS, was about to start restoring his old Heathkit HW-16, he decided it was time to explore what would be needed to key this tube rig using an electronic keyer. The key jack of this rig has a negative voltage, something like –85 V or more. Even the 2N7000 output of a solid-state keyer, rated at 60 V, would be no match for that. The Universal Keying Adapter (UKA) shown in **Figure 48** bridges the gap between a modern keyer and a classic tube-type transmitter, and

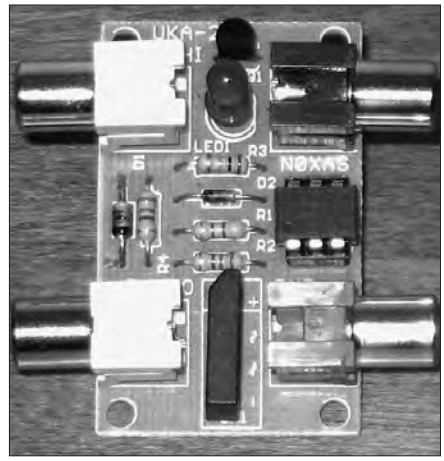

**Figure 48 — The Universal Keying Adapter 2. Parts count is low, and it can easily be built on a small project board. A newer version is available as a kit from www. hamgadgets.com.**

it can also be used to key older tube-type amplifier TR switching lines with solid-state transceivers that can't handle the voltage or current requirements.

### KEYING SCHEMES

Older gear generally uses one of two keying schemes, grid-block or cathode keying. Grid-block keying requires that your key handle fairly high negative bias voltages, often in the 150 V range. Cathode keying is more demanding, with voltages up to +350 V or so. Most modern solid state keyers use a simple transistor output circuit suitable only for low-voltage, positive keying. Obviously, neither grid-block nor cathode keyed transmitters should be connected to such an output! At the very least it's going to damage the keyer.

Most grid-block keying adapters use one or two bipolar transistors and are designed specifically to key grid-block rigs. This is fine as far as it goes, but also requires that you have one setup for solid state rigs, another for

grid-blocked rigs, and still another if you have a cathode keyed boat anchor as well. It's not an optimum solution. Of course one could use a relay to key just about anything, but relay contact noise would quickly get really irritating. Relays also eventually wear out, contacts get dirty and the coils can use quite a bit of current, meaning battery powered keyers will suffer from very limited battery life.

### Solid-State Relays

Solid state relays exist, but they can be expensive. The author finally hit upon what seems to be an ideal solution. It's cheap, small, relatively low current, uses low voltage control and is capable of switching fairly high ac or dc voltages. Perfect! Crydom, NEC, Fairchild, Omron and other manufacturers make very similar small, inexpensive MOSFET solid state relays. Suitable model numbers include the NEC PS7142 and PS7342, Fairchild HSR412, Omron G3VM-401B and others. Depending on the part selected they can handle up to a couple hundred milliamps and will switch up to 400 V ac or dc. All of this in a 6-pin DIP form factor, and for just a few bucks!

The MOSFET solid-state relay (SSR) is very similar to an optoisolator, but somewhat more versatile. Ac or dc loads can be switched, and the allowable load voltages are much higher than regular optoisolators. Driving the relay input involves supplying a few mA of current to turn on an LED inside the device. This requires about 1.4 V at a recommended forward current of 10 to 30 mA. The output is a pair of MOSFETs with common sources and a photo gate rather than a hard-wired gate. Turn on the LED and the MOSFETs conduct, turn off the LED and the MOSFETs shut off. Just like a relay, it's simple and elegant.

### KEYING ADAPTER CIRCUITS

The addition of a simple transistor inverter allows the use of computer keying in parallel with input from a straight key, bug or keyer. This is handy, for example, to contesters using computers for keying who may need to send some information by hand from time to time. See **Figure 49**. The use of a 2N7000 MOSFET instead of the common NPN transistor makes it easier to accommodate both serial and parallel port use, since the gate will withstand up to 20 V positive or negative and does not need to be current limited. In this example, the value of R1 should be determined as mentioned earlier. R2's purpose is to keep the MOSFET gate from floating, so its value is not critical but 10 kΩ or 100 kΩ are good values.

The design eventually evolved to include a full-wave bridge rectifier allowing either ac or dc input, a Zener diode for voltage regulation and an LED keying indicator. The result was the Universal Keying Adapter 2. The UKA-2 can accept any dc or ac power source up to about 30 V, and is adaptable to lower power battery operation by substituting or eliminating some of the power supply parts. A newer version is available in kit form from **www.hamgadgets.com**.

### OTHER CONFIGURATIONS

It is worth noting that if only positive or only negative voltages will be used, the output current capacity can be greatly increased and the on-state resistance greatly decreased by connecting the two MOSFET drain outputs in parallel rather than serial. An example of this is shown in Figure 49B. For the HSR412, maximum load current increases from 140 mA for series output to 210 mA for parallel. An added feature of this arrangement is the presence of the intrinsic "body diodes" of the MOSFETS. If you are keying an amp that has an internal keying relay, this can serve to absorb some of the back EMF when the relay releases. Note that this arrangement requires that pin 5 of the IC be at a lower voltage than the other two pins — in other words, ground for positive keying, or –V for negative keying. Since the output is completely isolated from the input, the polarity of the output connector can be changed without the risk of exposing your other gear to dangerous voltages.

Although the IC solid-state relays are good for a wide range of uses, there are applications that present more of a load than the device is able to safely handle even with the outputs in parallel. For loads of more than the rated device current, an external MOSFET switch can be used. Again, the resulting output is optically isolated from the input. Resistor R3 shown in Figure 49C keeps the gate of the 2N7000 MOSFET low until the input is activated, so its value is not critical. The gate voltage +V needs only to be within the safe range for the device selected; in most cases 12 V will do fine.

The UKA design works well with both grid-block and cathode keyed rigs, as well as solid state. It works quite well to key older tube power amplifiers with solid-state transceivers that are not equipped with suitable keying relays or circuits. The input works well with any rig, key, electronic keyer, serial or parallel port tried so far.

## 11.2 Interfacing High-Voltage Equipment to Solid-State Switching Circuits

More is required to connect HV (high-voltage) vacuum-tube gear to solid-state

accessories than a cable and the appropriate connectors. The solid-state switching devices used in some equipment will be destroyed if used to switch the HV load of vacuum tube gear. The polarity involved is important too. Even if the voltage is low enough, a key-line might bias a solid-state device in such a way as to cause it to fail. What is needed is another form of level converter.

## MOSFET LEVEL CONVERTERS

While relays can often be rigged to interface the equipment, their noise, slow speed and external power requirement make them an unattractive solution in some cases. An alternative is to use power MOSFETs. Capable of handling substantial voltages and currents, power MOSFETs have become common design items. This has made them inexpensive and readily available.

Nearly all control signals use a common ground as one side of the control line. This leads to one of four basic level-conversion scenarios when equipment is interconnected:

1) A positive line must be actuated by a negative-only control switch.

2) A negative line must be actuated by a positive-only control switch.

3) A positive line must be actuated by a positive-only control switch.

4) A negative line must be actuated by a negative-only control switch.

In cases 3 and 4 the polarity is not the problem. These situations become important when the control-switching device is incapable of handling the required open-circuit voltage or closed-circuit current.

Case 1 can be handled by the circuit in **Figure 50A**. This circuit is ideal for interfacing keyers designed for grid-block keying to positive CW key lines. A circuit suitable for case 2 is shown in Figure 50B. This circuit is simply the mirror image of that in Figure 50A with respect to circuit polarity. Here, a P-channel device is used to actuate the negative line from a positive-only control switch. The values of R1, R2, and the Zener voltage for D1 must be determined based on the keying device.

Cases 3 and 4 require the addition of an inverter, as shown in **Figure 51**. The inverter provides the logic reversal needed to drive the gate of the MOSFET high, activating the control line, when the control switch shorts the input to ground.

Almost any power MOSFET can be used in the level converters, provided the voltage and current ratings are sufficient to handle the signal levels to be switched. A wide variety of suitable devices is available from most large mail-order supply houses.

# 12 PICAXE-Based Timer

This project by Darrell Davis, KT4WX (**www.kt4wx.org**) was originally published in the April 2016 issue of *QST*. The full article, including programming details, a flow chart for the software, and associated files are included in this book's downloadable supplemental information.

This PICAXE microcontroller-based timer is a programmable replacement for analog IC-based timers. It is a simple design that is an excellent "first microcontroller" project if you are unfamiliar with microcontrollers and software development. The program has two timer modes — 3 minutes (for repeater use to prevent timeouts) and 10 minutes (for extended QSOs to satisfy FCC requirements for station identification).

The time schematic diagram in **Figure 52** is based on the low-end eight-pin PICAXE 08M2 microcontroller. Pin 1 is $+V_{cc}$ and pin 8 is ground. The circuit uses three discrete LEDs controlled by pins 3, 5, and 6 to indicate timer status. Pin 7 is used for serial outgoing data to a programmer and pin 2 is the incoming data from the programmer. R1 and R2 control the voltage at pin 2 to prevent the input from "floating" when the programmer is not connected which could cause unstable operation. Pin 4 acts as a reset input along with pull-up resistor R3 and switch S2.

Construction is not critical and the circuit can be assembled using point-to-point wiring on perfboard as shown in **Figure 53**. The assembled circuit can be installed in a standalone enclosure or used as a module in a larger project. If the LEDs are separated from the controller assembly by more than an inch or two, add 0.01 µF ceramic capacitors across the diodes to prevent RFI to the circuit or from the LEDs rectifying a strong local RF signal and generating harmonics.

Any voltage source from 3 to 5 V dc with a 50 mA capacity is adequate to power the circuit. A 7805-based regulator is included in the schematic. A lithium-ion battery such as a CR2032-style coin cell can be used to power the circuit for portable or mobile use as shown in Figure 52.

# 13 An Arduino-Based Knob Box for SDR

The following section is based on the article of the same name by Michael Stott, VE3EBR, first printed in the Radio Amateurs of Canada magazine *The Canadian Amateur* (*TCA*). The complete article and supporting files are provided with the downloadable supplemental content and online at the websites referenced in the article.

SDR equipment is becoming more and more popular with amateurs, displacing analog electronics and changing the way amateurs operate and even think of the radio spectrum. The user interface of most SDR radios is implemented as a PC screen with mouse and keyboard controls that are easy and inexpensive to implement but not always the most responsive or intuitive way of controlling or performing a function — a physical knob or switch often works better for frequently used functions.

VE3EBR created the "SDR Knob Box" to replace some of the Flex-5000's *PowerSDR* screen controls with knobs and switches. An Arduino interfaces with the knobs and switches, then sends the appropriate commands to the computer software (*DDUtil*) which then controls the SDR. In addition, switches and indicators are also included for controlling a standalone Yaesu rotator in association with the *DXLab* software.

Based on the Arduino microprocessor with all of its supporting software tools and hardware accessories, this project lends itself well to being adapted to any set of functions desired for an SDR transceiver or any computer-controlled device.

The author discovered an article by Anthony Good, K3NG, that describes an Arduino-based interface/controller for the rotator and decided to use this design as the basis for adaptation. The whole unit is powered from the Arduino USB connection.

## HARDWARE DESIGN

The knob box is based on three small potentiometers, a pair of ¼-inch-bushing toggle switches, and a rotary shaft encoder with 24 detents and a nice silky "feel" to it (Panasonic EVQ-VBMF0124B/ Digikey P80685-ND). **Figure 54** shows the schematic of the knob box hardware.

The three potentiometers are allocated to Audio Gain, RF Gain (AGC-T on the author's Flex 5000), and RF Drive, arranged vertically to correspond to the control positions on the *PowerSDR* "panel." One of the toggle switches had a center-OFF position so it was allocated to TX/RX/Tuneup and a two-position switch to Monitor ON/OFF. The mechanical shaft encoder was dedicated to tuning the RF frequency. Red and green LEDs to show which direction the rotator was turning were mounted on the box panel using rubber grommets.

The selection of type and number of controls is pretty arbitrary and one could accommodate almost any combination within the limits of the Arduino's six analog inputs, eight digital I/O ports, and six digital I/O/

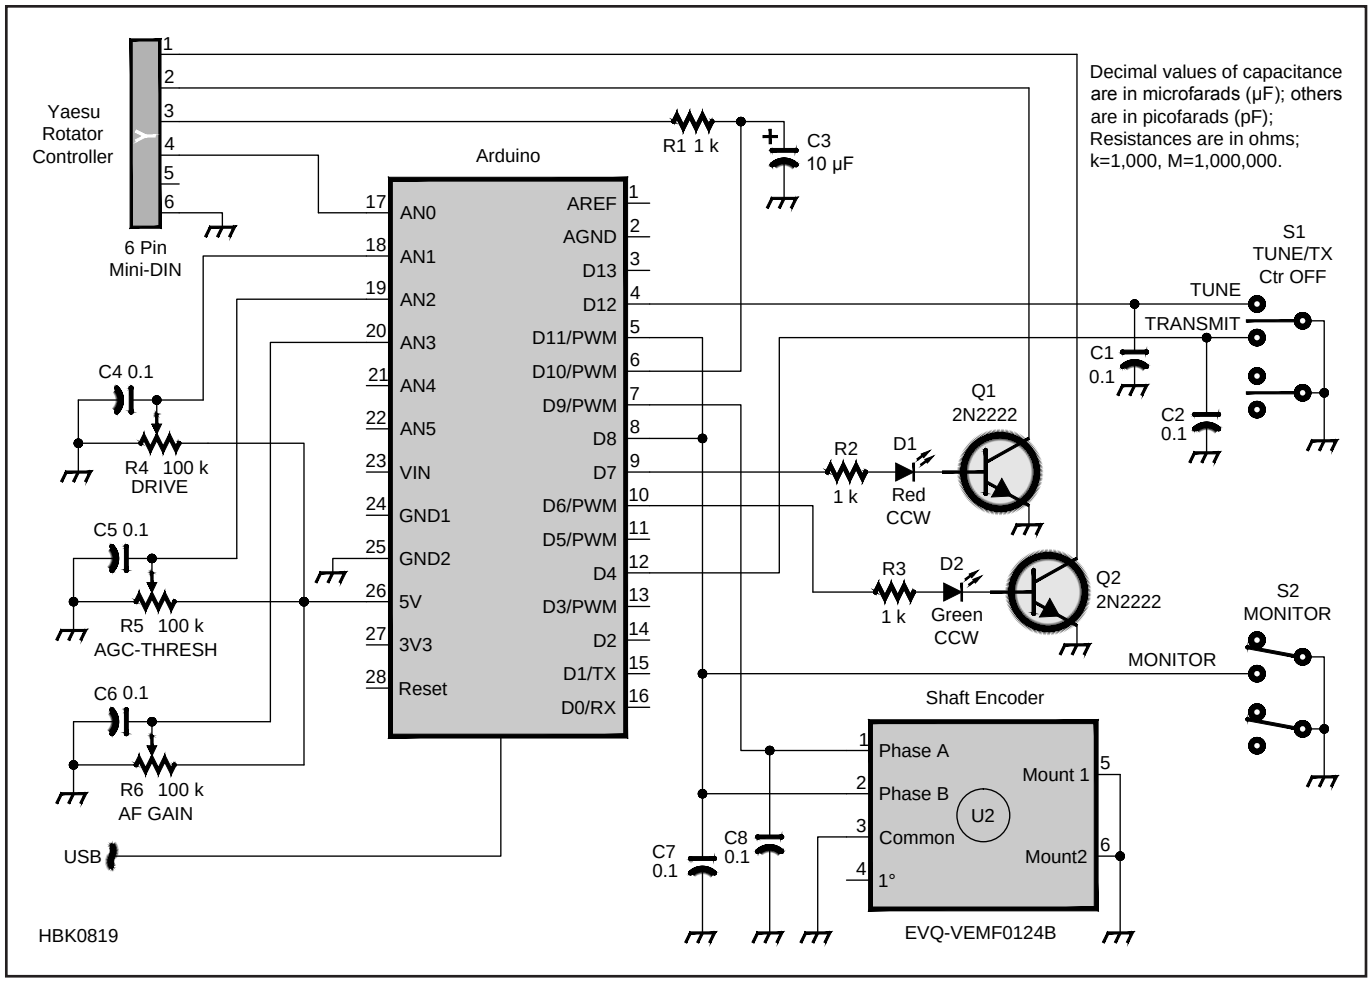

**Figure 54 — The schematic of the SDR Knob Box showing how to connect a shaft encoder, potentiometers (R4, R5, R6), and switches (S1 and S2) to the Arduino microcontroller.**

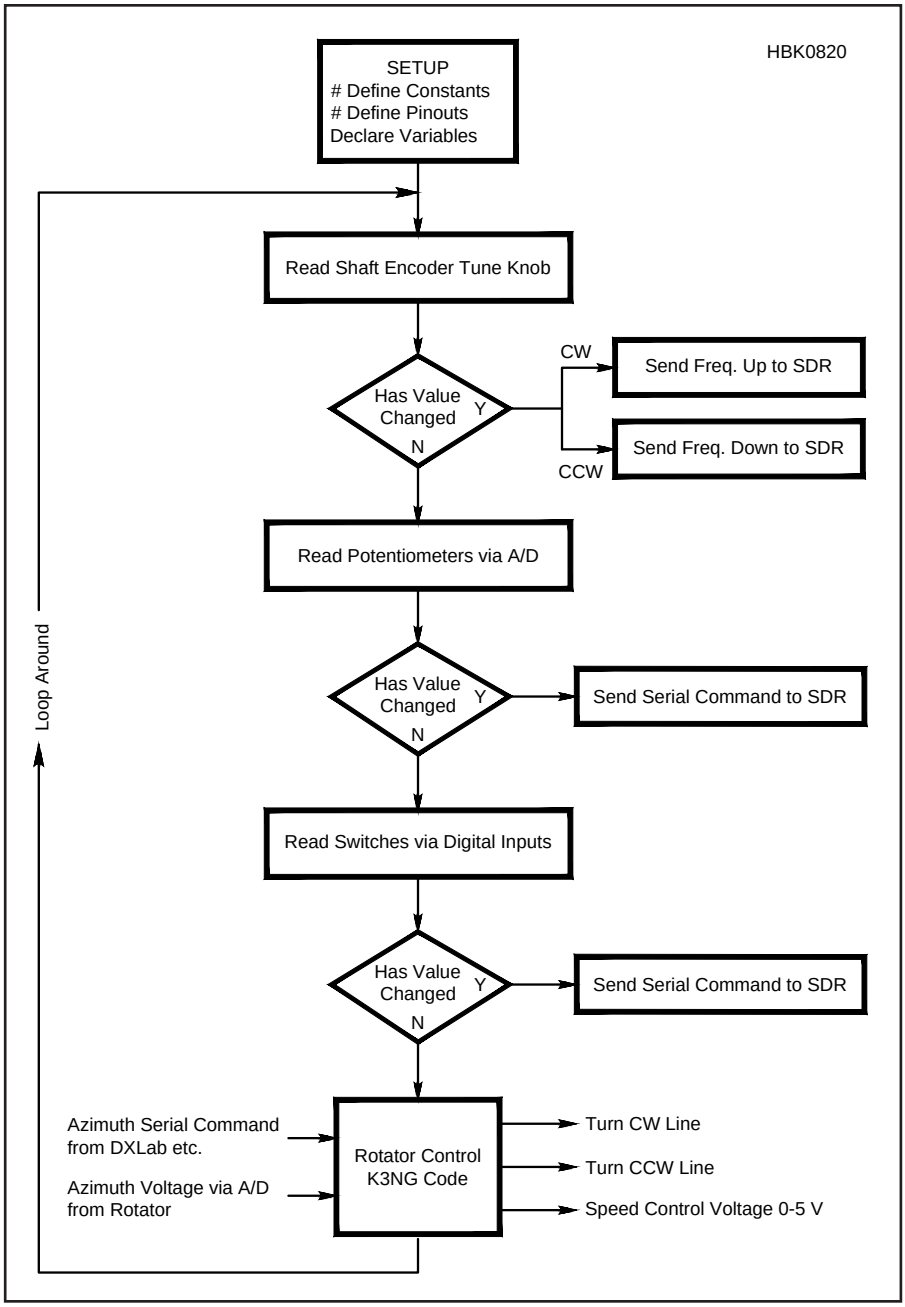

**Figure 55 — Flow chart showing the control loop for the Arduino microcontroller. Once the setup process is complete, the software enters and remains in a loop to sense changes of the control positions or settings and generate commands to the SDR transceiver accordingly.**

**Figure 56 — The SDR Knob Box replaces software controls such as click boxes and sliders with physical knobs and switches read by an Arduino microcontroller and then relays the appropriate commands to an SDR transceiver.**

PWM_analog_outputs. Shaft encoders could be used rather than potentiometers but the "absolute" nature of the potentiometer position lends itself well to controls for setting levels rather than the relative or incremental output of an encoder, which is better suited to controlling changes such as tuning.

## SOFTWARE DESIGN NOTES

Software for the unit was created by grafting on the code for responding to the potentiometers, switches, and so forth onto the K3NG rotator controller code. When the unit is switched on, the program stored in the onboard flash memory of the Arduino loads automatically and executes. It runs all the setup functions once and then begins a continuous looping process as shown by the flow chart in **Figure 55**. (All C language code is available at **wp.rac.ca/tca-content**.)

The functionality is quite simple. The Arduino reads the status of the various knobs and switches and compares the most recent state to the previous state. If something has changed it outputs a command to the SDR; otherwise it does nothing and continues looping.

The SDR software communicates with external programs by means of virtual COM ports and Virtual Audio Cables. The SDR interface utility software is *DDUtil* (version V3.x was used in the development of this project) is required. This free software provides a host of interfacing facilities between accessory equipment, rotators, digital mode software, and the Flex-5000 CAT computer control port. **Figure 56** shows the completed Knob Box.

# 14 An Audio Intelligibility Enhancer

Here's a simple audio processor (**Figure 57**) described by Hal Kennedy, N4GG, that can improve intelligibility, particularly for those with degraded high-frequency hearing. It might just give you an edge in that next DX pileup.

What we understand (intelligibility) of what we hear or detect is strongly affected by the end-to-end frequency response of a given communications circuit. Our equipment typically has a fixed audio bandwidth spanning about 300 Hz to 2700 Hz for SSB operation, but our hearing varies widely from operator to operator and it sometimes varies widely for an individual over the course of his or her life.

Speech intelligibility has been studied extensively since the 1940s. In brief, the "human speech signal" can be thought of as being made up of vowel and consonant sounds. The vowel sounds are low in frequency, with fundamental frequencies typically between 100 Hz and 400 Hz, and harmonics as high as 2 kHz. Consonant sounds occupy higher frequencies — typically from 2 kHz to as high as 9 kHz. (See "Speech Intelligibility Papers" at **www.meyersound.com/support/papers/speech/**). In spoken English, vowel sounds contain most of the energy in the speech signal, while consonant sounds are short, noise-like, and convey the majority of intelligibility. When consonants are not heard well, it sounds like the speaker is mumbling. It becomes difficult to distinguish *F* from *S* and *D* from *T*.

Frequently, hearing degradation manifests itself both as a loss of sensitivity over all frequencies and a frequency dependent loss where the sensitivity of our hearing degrades as the frequency increases. Sensitivity loss that is flat over frequency does not affect intelligibility, assuming that levels are high enough to be heard. A simple loss of sensitivity can be addressed by turning up the AF gain! Unfortunately, turning up the gain does not compensate for frequency-dependent loss, and frequency-dependent loss does degrade intelligibility by reducing the ability to hear the consonants in human speech. A quick Web search for "human hearing" will yield a multitude of sites describing the basic concepts.

The author's audiology test results are shown in **Figure 58**. Audiologists refer to this pattern as *age induced hearing loss* — a roll-off of hearing sensitivity as frequency increases. Fortunately, intelligibility can be improved significantly for those with this common condition, by simply adding amplification that increases as a function of frequency.

Hearing deficiencies can be much more complex than the typical high frequency loss associated with aging. One's hearing can include notches and/or peaking as a function of frequency, as well as significant mismatch between the left and right ears. Most of these can be addressed through use of audio circuits whose gain approximates the inverse function of the hearing problem(s). Analog circuit designs become complex when more than a simple high-pass or single-notch filter is required. Modern high-end hearing aids use DSP circuits that break the audio spectrum into narrow frequency bands, each with programmable gain.

A professional audiology exam and threshold sensitivity test results are recommended as the starting point for determining how much, if any, audio shaping might improve your ham radio activities.

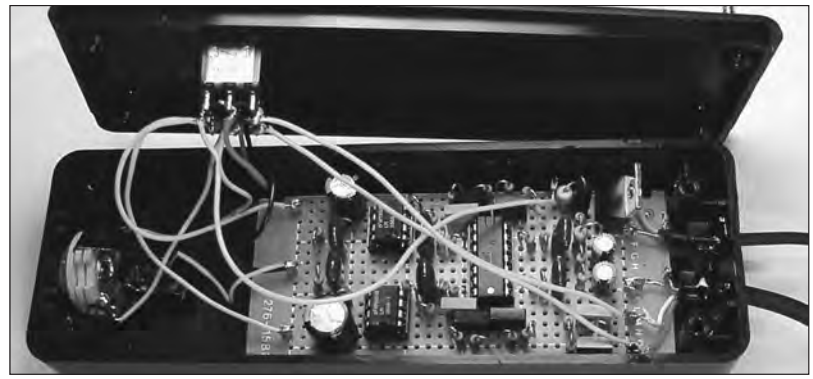

**Figure 57 — The audio intelligibility enhancer is a compact audio processor that can help to compensate for degraded high-frequency hearing.**

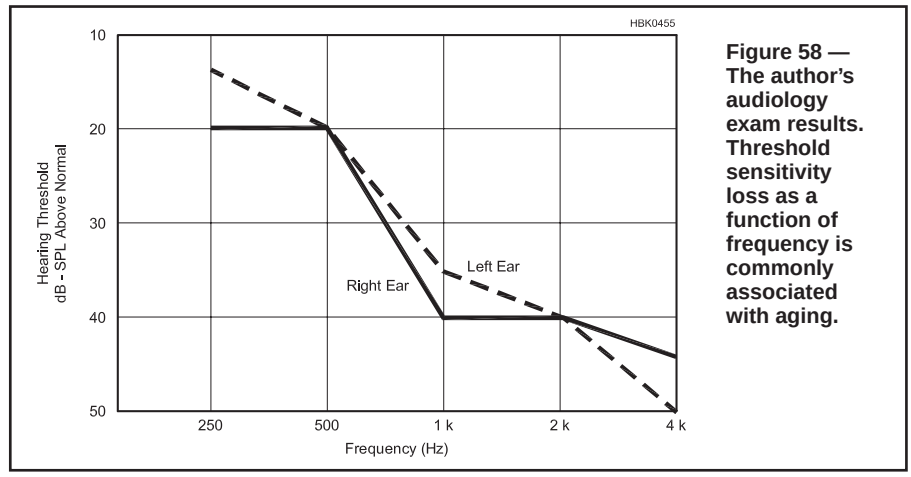

**Figure 58 — The author's audiology exam results. Threshold sensitivity loss as a function of frequency is commonly associated with aging.**

## A VARIETY OF PRACTICAL OPTIONS

The author's operating interests require stereo operation to make significant use of a transceiver's dual receiver function when chasing DX, and to operate two radios simultaneously in contests. In each case operation is in stereo, with each ear dedicated to one of the two receivers. Monaural designs also have a potential drawback, in that the frequency response adjustments apply equally to both ears. In some cases the frequency response of each ear is different.

Stereo equalizers have been around for decades. The most basic are four-band graphic equalizers; they have adjustments to provide up to about 12 dB of gain or attenuation across frequency bands that are centered at four frequencies, each frequency typically one octave above the next (an octave is a doubling of frequency). Seven, 10, 12 and 15 band equalizers are readily available, allowing for finer tailoring of amplification characteristics as the number of bands go up and the frequency range for each band gets smaller.

Parametric equalizers are also available — these differ from graphic equalizers in that the center frequency and bandwidth of each filter element is adjustable. Prices are very reasonable.

An equalizer is a near-perfect solution to compensating for hearing deficiencies, and the ability to readily adjust gain at multiple frequencies allows optimizing via experimen-

tation. Many equalizers are strictly low-level devices and lack sufficient output power to directly drive headphones, requiring an amplifier if the equalizer is to be inserted between rig and headphones.

Some transceivers include adjustable audio DSP circuits for receive as well as transmit audio. It may be possible to adjust the audio response of your transceiver to improve intelligibility without the use of an external device.

## CIRCUIT DESCRIPTION

The heart of this audio intelligibility enhancer (AIE) is what audiophiles refer to as a *high-pass shelving filter*. Shelving filters are sometimes used in high-end audio systems to compensate for deficiencies in crossover networks or loudspeakers. The basic circuit and its frequency response are shown in **Figure 59**. Note that the shape of this response curve is the inverse of the hearing response of Figure 58. Referring to Figure 59, the circuit provides a gain, $A_{V1}$, equal to 1.0 for frequencies somewhat below $f_1$ and a higher gain, $A_{V2}$, that is given by $A_{V2} = 1 + R2/R1$ for frequencies somewhat above $f_2$. Frequency $f_1$ is given by $f_1 = 1/[2\pi C(R1+R2)]$, and frequency f2 = $1/(2\pi CR1)$. Conveniently available component values of R1 = 1.33 kΩ, R2 = 6.65 kΩ, and C = 0.047 µF yield a high frequency gain, $A_{V2} = 6.0$, and cut-on and cut-off frequencies of $f_1 = 425$ Hz, and $f_2 = 2550$ Hz. With these values, the circuit gain rises at an average of 3 dB per octave from 300 Hz to 2700 Hz — the frequency range for SSB transmission. For those interested in modifying the design, or using a shelving filter for other purposes, it's important to note that rearranging the equations yields: $f_2/f_1 = A_{V2}$. The ratio of the two break frequencies always equals the maximum gain.

Figure 59 also shows a feedback capacitor, $C_f$, which, while not contributing to the shelving filter function, is included as good design practice. The LM324 op amps used to implement the filters have gain-bandwidth products in excess of 1 MHz. Operating them with gain at frequencies above the useful limits of our hearing (and all the way out to beyond 1 MHz) is an open invitation for RFI prob-lems and unwanted high frequency noise. So, feedback capacitor $C_f$ provides high frequency gain roll-off above the frequency $f = 1/(2\pi C_f R2)$ which for the value of $C_f$ in this design (0.0015 µF) is 16.8 kHz.

**Figure 60** is the complete schematic for the AIE. Two shelving filters, as described above, are used in series in each audio channel. Two filters in series provide sufficient gain change versus frequency to approximately match the author's high frequency hearing loss, which has a slope of about –7.5 dB/octave across the audiologist's measuring points from 250 Hz to 4 kHz. Two filters in series provide +6 dB/octave gain change from 300 Hz to 2700 Hz and 31 dB of total gain ($A_{Vtotal} = A_{V2} \times A_{V2} = 6 \times 6 = 36$ or about 31 dB). Some tips for tailoring the circuit to your hearing are included in the next section.

The shelving filters are followed by LM386 audio amplifiers (U2, U3). These provide sufficient output power to drive headphones or small speakers. LM386s have a built-in voltage gain of 20, so they are preceded by 20:1 voltage dividers (R7+R8, R17+R18) to maintain an end-to-end gain of 1 at low frequencies.

Voltage regulator U4 provides regulated and filtered dc voltage to the shelving filters and the output stages. Current draw for the AIE is approximately 35 mA from a +13.6 V dc source, if the LED pilot light (D1) is included. D1 draws 10 mA by itself, however, and R21 and D1 can be deleted if current consumption is a concern. Supply voltage is not critical — anything from 12 to 18 V dc will work.

Capacitors C1 and C10 are used to prevent RFI, by bypassing to ground RF that may enter at the inputs. The original AIE without these capacitors suffered interference from loud distorted sounds (unrectified SSB RF) during transmit. C1 and C10 eliminated RFI problems, but they could be insufficient in the presence of large RF fields. If necessary, additional RF filtering can be achieved by adding RF chokes in series with both audio input and output lines.

## TAILORING THE DESIGN TO YOUR HEARING

The AIE design presented here is intended to address high frequency hearing loss, and not other hearing deficencies. This AIE design does, however, have a reasonable amount of flexibility for tailoring to an individual's hearing.

The design as it is presented in Figure 60 includes two shelving filters per channel and switch S1. S1 allows selection of one (3 dB/octave amplification) or two (6 dB/octave amplification) filter stages. If you are the only operator of your station and you know your hearing deficiency is less than about 5 dB/octave, the switch and the second filter in each channel can simply be eliminated. If you are unsure of how much high frequency amplification you might need, or in the case where more than one operator may be sharing a station, the switch and the second stages will prove useful. S1 could also be replaced with two switches — one for each channel — if your high frequency hearing is not similar in both ears.

For gain slopes other than 3 dB/octave or 6 dB/octave, one or both filters in either channel can be modified using the equations given earlier. Taking this further, one or both of the op amps in either channel do not have to be shelving filters — they can be used to implement a variety of other filter functions including notching, peaking, or multi-pole functions. Op-amp filter design is covered

extensively in circuit design handbooks and on the Internet.

In addition to tailoring the gain change versus frequency, the overall gain of each channel can be adjusted to compensate for the sensitivity differences between ears. Overall gain is adjusted by changing the voltage dividers R7+R8 and R17+R18. R8 and R18 can also be replaced with 5-kΩ potentiometers if adjustable gain is desired.

When considering changing the design, it's important to know that human speech recognition is remarkably tolerant of deviations from an ideal amplitude versus frequency response curve. Also, personal preference comes into play — you may hear more comfortably with less than complete compensation for high frequency hearing loss. Although 6 dB/octave compensation closely matches the author's hearing loss, he usually has the AIE switched to 3 dB/octave compensation. At this setting, intelligibility is improved considerably.

## CONSTRUCTION

With a few exceptions, the layout of the component parts is not critical. The leads on the IC power decoupling capacitors (C22, C23, C24) and all leads to the op amp inputs should be kept as short as possible. Be sure

to make the U1 power connections at pins 4 and 11.

The completed AIE is shown in **Figures 61** and **62**. The prototype is built on a grid style PC board with 0.1 inch centers cut to fit snugly in a 6×2×1 inch plastic project box. Parts numbers for the PC board and the project box are included in the parts list. A PC board is available from FAR Circuits (**www.farcircuits.net**).

Two cautions are in order. First, building an AIE as small as the prototype requires small tools, a large magnifying glass and patience. Since the circuit design is not particularly sensitive to layout, consider using a larger layout and a larger enclosure. The second caution is with regard to using a plastic enclosure. Susceptibility to RFI and 60 Hz hum pickup will be greatly reduced by using a metal enclosure. If you have lots of RF in your shack you may have no choice but to use a metal enclosure.

Components are readily available from online suppliers such as Mouser or DigiKey. Several substitutions can be made if needed. The 1.33-kΩ resistors can be made from a 1-kΩ and a 330 Ω resistor in series; the 6.65-kΩ resistors can be made from two 3.3-kΩ resistors in series, and the 1.5-kΩ resistor can be made from a 1-kΩ and a 470 Ω resistor in series. The value of the 0.0015 µF feedback capacitors is not critical (C3, C5, C12, C14) — 0.001 µF disk ceramics can be substituted.

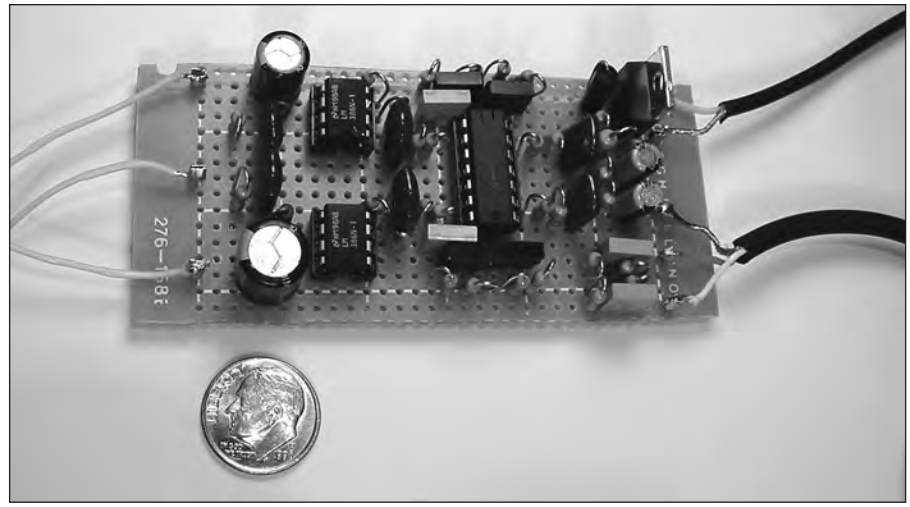

**Figure 61 — A close-up of the AIE before mounting in the project box. It all fits neatly within a 6×2×1 inch enclosure if you have the patience to build within tight spaces.**

**Figure 62 — The AIE takes up little desk space. It plugs inline between the transceiver and headphones and requires 13.6 V dc. In the author's shack, the unit is powered from a transceiver accessory jack and is always switched on.**

## HOW WELL DOES IT WORK?

Intelligibility is absolutely crucial to maintaining high QSO rates and correct logging in contests, and in pulling the weak ones out of the noise when DXing or operating in less-than-ideal conditions. The AIE has provided the author with an immense improvement in both activities. It's just as helpful for reducing listening fatigue during ragchewing or general listening as well.

A real surprise was how much intelligibility improved on CW. This may seem counterintuitive at first, if you view "continuous wave" as comprising a single frequency. From a communications standpoint, however, the CW waveform is not continuous — it is comprised of elements — dots and dashes. The leading and trailing edges of each element are made up of frequencies higher than the carrier frequency, and hearing these helps the listener separate one element from the next. When the rise and/or fall times of the elements are very fast compared to the carrier frequency, the high frequency content of the waveform becomes sufficiently large to cause key clicks. Very slow rise and/or fall times produce the opposite of clicks — a sound that experienced CW operators describe as "mushy." Mushy code is very difficult to copy, particularly at high speeds, because the ability to decipher when an element has started or stopped has been reduced. Degraded high frequency hearing has the same detrimental effect on CW intelligibility as slowing down the waveform edges — it makes a properly formed CW waveform sound mushy. The AIE restores perception of the waveform edges in CW, just as it does for speech.

How much an AIE or any other approach to compensating for your hearing deficiencies will help you depends, to a large degree, on the state of your hearing. The more you have lost, the more you have to gain back. Audio shaping may also offer some intelligibility improvement if your hearing is within normal limits. Typical receiver bandwidths are narrower than the audio range needed to fully support intelligibility — some of this can be gained back with high frequency amplification.

One cautionary note from Jim Collins, N9FAY, a designer in the hearing aid industry. At low volume levels, a device such as the AIE is helpful in improving intelligibility. At high volume levels, the audio will start to sound "tinny." This happens because as sound levels increase, the corrective frequency curve must flatten. At upper sound levels of comfortable hearing, it becomes almost a flat line with unity gain, In other words, the hearing response is close to normal at high sound levels. If a device like the AIE is used for prolonged periods at high volume levels, it may accelerate hearing loss at upper frequencies. For more discussion, see Technical Correspondence in May 2005 *QST*, p 70.

# 15 An Audio Interface Unit for Field Day and Contesting

For Field Day and multioperator contest operation, it's sometimes desirable for a logger or observer to listen to a transceiver in addition to the main operator. The project shown in **Figure 63**, by John Raydo, KØIZ, makes two-person operation more efficient. Dual stereo headphone jacks, volume controls and an external speaker jack are provided, as well as jacks for both dynamic and electret microphones and an intercom feature for operator and logger to more easily communicate via headset mics.

There are times when the operator and logger need to talk to each other, for example to resolve a call-sign ambiguity. With this unit the operator can initiate two-way intercom communication by closing an intercom switch. The logger, however, can only initiate one-way intercom to the operator. This is so that the logger can't inadvertently cut off the operator during a contact. To respond, the operator closes his intercom switch. In both instances, radio volume is reduced for "talk-over" during intercom use.

Both the operator and logger need headsets with microphones. The unit has two intercom switches plus jacks for optional foot switches for hands-free operation. Here's how it works:

*Operator communicating with the logger:* The operator presses and holds the OPERATOR TALK switch (S3 on the unit or by using a foot switch connected to J4). This disconnects the operator mic from radio. Both mics are connected via an internal amplifier to both headphones. Radio volume is reduced (adjustable using the RADIO VOL control). Operator and logger can talk to each other.

*Logger communicating with the operator:* The logger presses and holds the LOGGER TALK switch (S4 on the unit or by using a foot switch connected to J5). Logger mic is connected via an internal amplifier to both headphones. Operator mic remains connected to radio and can still transmit on the radio. Radio volume is reduced. The operator can respond to the logger by pressing the OPERATOR TALK switch.

## CIRCUIT DESCRIPTION

The circuit diagram shown in **Figure 64** is designed for use with dynamic microphones such as the HC4 and HC5 elements used in various Heil headsets, or for Heil iC type headsets that use an electret element. The electret mic jacks supply the required dc for that type microphone. Mic bias current is limited to less than 1 mA to avoid damage if a dynamic mic is accidentally plugged into the wrong jack. The higher electret output is reduced by resistors R11 and R28.

Both mics have preamplifiers with 34 dB gain set by the ratio of the resistors R4/R3 and R9/R8. The INTERCOM volume controls, R14 and R15, allow operator and logger to individually adjust their intercom volumes. The preamps feed a single 2-W intercom amplifier.

Closing the OPERATOR TALK switch transfers the operator mic from radio to intercom preamp and amplifier via K1 and then to the headphones via K2. Pressing the LOGGER TALK switch will also activate K2 (but not K1). During intercom use, audio from the radio passes through control R20 (RADIO VOL) at reduced volume. S2 (L+R) allows selection of both left and right sides of the headphones or only the right side, for the intercom. The operator and logger each have individual headphone PHONE VOL controls R24 and R25 (the operator control also incorporates the POWER switch, S1).

## CONSTRUCTION

The unit shown is built in a PacTec plastic box. The front panel has the control switches and volume controls described in the previous section. The back panel (**Figure 65**) has ¼-inch stereo jacks for two pairs of headphones, two 3.5-mm mono jacks for headset microphones, 3.5-mm stereo and mono jacks for connection to the radio's headphone and mic jacks, one stereo 3.5-mm jack for a speaker, two 3.5-mm mono jacks for foot switches and a jack for a 9-V power supply (a wall wart is okay). A 12-V dc supply can be substituted if K1 and K2 are changed to 12-V units and the LED series resistors R22 and R23 are changed to 1 kΩ.

Other than controls and jacks, most components are mounted on a prototype circuit board supported by four ½ inch spacers and shown in the box in **Figure 66**. A suggested parts layout is shown in **Figure 67**. Point-to-point wiring is used between circuit board pads and is not particularly critical. A PC board for this project has been developed by FAR Circuits (**www.farcircuits.net**).

Connections to both mic jacks and the radio mic jack use shielded cable to reduce hum and risk of interference pickup. Connect the shields on the operator and radio mic cables to a common ground point on the circuit board near U1. Bypass capacitors C8, C9 and C16 and resistor R6 are mounted at their respective jacks. Rub-on lettering, followed by a couple light coats of clear plastic spray, helps give a professional appearance.

Connecting an external speaker in addition to two headphones might be too much of a load for some radios and cause reduced volume and/or distortion. Try an inexpensive amplified computer speaker plugged into the audio interface external speaker jack to reduce the load.

You will need two cables to connect the unit to your radio. A 3.5 mm mono plug-to-plug shielded cable for the mic circuit is compatible with a Heil headset mic. A 3.5 mm stereo plug-to-plug cable works for the earphones.

# 16 Two QSK Controllers for Amplifiers

Many CW operators feel that QSK — or *full break-in* — operation is the most natural and conversational way to operate. "Full" break-in switches between transmit and receive so quickly that the operator can hear anything happening on the channel between individual code element dots and dashes. (*Semi break-in* uses a VOX-like circuit, remaining in transmit until a delay timer expires.) That sense of transparency enables the operator to respond immediately to interference or requests from other stations. Originally developed in support of high-speed CW traffic passing, QSK today is most often used by contest operators and for high-speed ragchews.

For low-power operation at 100 to 200 W, QSK circuits can use relatively small relays or solid-state PIN diode switches. However, when an amplifier is used, the requirements for voltage and current-handling go up dramatically. This leads, in turn, to the use of vacuum relays and high-power PIN diodes. *Hot-switching* — opening or closing mechanical contacts during current flow — greatly accelerates wear and can even destroy the relay contacts. Preventing hot-switching requires strict timing and interlock design to make sure the proper sequence of switching-then-transmitting occurs every time.

QSK controllers generally fall into one of two general types: hardware-only, in which the timing and logic of the sequential operations are built-in to a hard-wired circuit, and software, in which the switching circuits are under the control of a microprocessor. This pair of QSK controllers includes one from each camp: Jim Colville, W7RY, designed an analog controller and Paul Christensen, W9AC, programmed an Arduino processor for his controller. You can choose to implement whichever project you feel most comfortable with. We'll begin with an overview of QSK operation by W7RY and then present both projects.

## SAFETY

Should you decide to add QSK to your amplifier, you'll be working inside the amplifier. Safety is the top priority in working on any equipment that contains high voltage, such as a vacuum tube amplifier. The shorting straps and interlocks are there for your safety, please respect them and be very careful! Read and follow the recommendations of the High Voltage Techniques section of the **Power Sources** chapter and the **Safety** chapter of this book.

Also be sure to operate the amplifier with all shields in place. You don't want to exceed the MPE (maximum permissible exposure) of RF energy to your body. And you just never know when the cat is going to jump up on your workbench!

## BASIC QSK PRINCIPLES

How is QSK different from PTT or semi-VOX operation in an amplifier? When switching is controlled by manual use of a PTT switch, the amplifier relays are usually energized long before the RF is output by the transmitter. With semi break-in, the receive/transmit transitions are usually between words or syllables rather than between dots and dashes.

Several things have to happen quite quickly with QSK, especially when you're sending CW at 30 WPM!

1. Switch the amplifying device bias from cutoff to the proper operating bias setting in less than 2 milliseconds.

2. Switch the RF relays from the bypass mode (in which the transceiver is connected directly to the antenna and the amplifier is biased OFF) to the transmit mode (in which the antenna is connected to the amplifier output and the transceiver is connected to the amplifier input). This must happen before RF starts flowing from the transceiver into the amplifier. (We are assuming the use of a modern transceiver for the remainder of this discussion. The same principles apply in switching separate receiver-transmitters.) **Figure 68** shows the basic relay wiring for a QSK system.

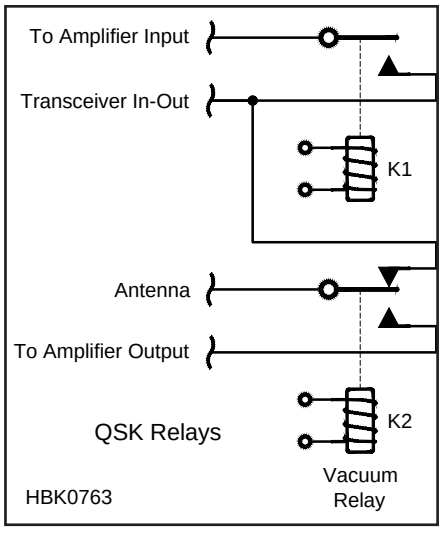

**Figure 68 — Basic organization of relay switching for QSK.**

This design uses only a single-throw relay for routing transmitter output to the amplifier input. Using a double-throw relay with another contact for receive adds another opportunity for the contacts to become intermittent in the receive path. Henry Radio used the approach of Figure 68 for all of their later production runs of amplifiers. Relay contact materials that are rated for transmitter output levels can become intermittent at the extremely low levels of received signals.

### Basic Timing Considerations

When the key or keyer paddle is pressed, several things happen in the transceiver. First, the key or paddle state must be read by the rig's keyer or microprocessor. The transceiver then switches into transmit mode, which mutes the receiver, switches the amplifier keying circuit, and starts to output RF. Most modern transceivers have the option (usually a menu selection) for either a mechanical relay or FET amplifier keying circuit.

Proper QSK operation depends on the delay between when the transceiver's linear amplifier keying relay energizes (after contact bounce has stopped) and when the radio starts to transmit RF. This delay, which is easily measured, is the key element in control of linear amplifier antenna relay and bias switching. The author has measured many modern transceivers such as the ICOM IC-7600, IC-751A, IC-7200, IC-756 PRO-II, and IC-756 PRO-III. All of these transceivers typically have a delay from final contact closure to RF output of about 4 to 6 milliseconds, shown for the IC-7200 in **Figure 69**. (The IC-751A is actually adjustable with an internal control.) The timing in SSB and RTTY seems to follow the CW timing in most radios.

The same process works in reverse when going from transmit to receive. RF output stops, the amplifier switching circuit changes back to receive, and the receiver is un-muted. This delay is typically a bit longer and **Figure 70** shows the IC-7200 delay, measured at about 6 ms.

If PIN diodes are used for switching the RF, speed is generally not an issue as the diodes switch in microseconds. If electromechanical relays are used, however, the few milliseconds available when going from receive to transmit require a fast relay. Reed relays are typically used for low power, such as the output of the transceiver, and are fast enough to use for QSK. Higher power, high-speed vacuum relays must be used at the amplifier output. These relays open and close in around 1 ms and are rated for millions of open-close cycles.

All mechanical relays and switches have contact bounce because of flexing in the relay's moving armature. Contact bounce is clearly visible with an oscilloscope when measuring the time it takes for a relay to close or open. All of the measurements in this article include the contact bounce time until the contacts are ready for power. A more detailed discussion of modifications to speed up the relay circuits is available in the PDF article "W7RY QSK Relay Timing" also included with the downloadable supplemental content.

Proper control of switching timing has benefits other than operational convenience. As W7RY relates, "After adding QSK to a Drake L-4, a Kenwood TL-922, and a Heathkit SB-200, the pesky arcing in the tuning capacitor stopped. The TL-922 was especially prone to it and the Heathkit SB-200 did it quite often when I was checking out the amplifier after I had purchased it. What happened?

"The arcing stopped because the amplifier was no longer hot-switching the relays and

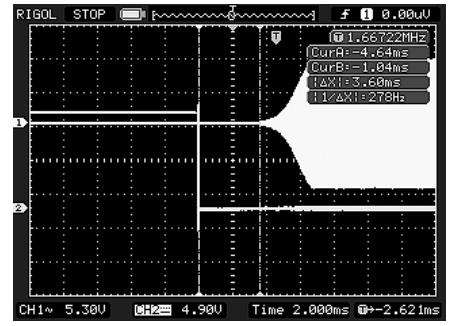

**Figure 69 — The relay-close-to-RF timing for an ICOM IC-7200. RF output appears 3.6 ms after the amplifier relay contacts close. The relay-to-RF time can be increased 1.5-2.0 ms by substituting a small switching transistor for the relay.**

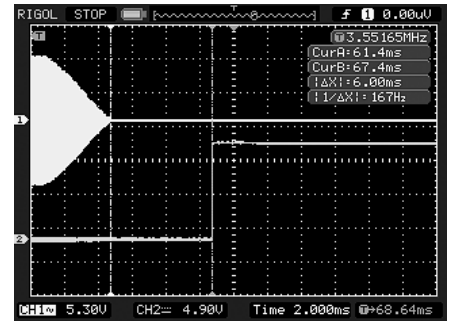

**Figure 70 — The same ICOM IC-7200 timing from RF-stop to relay contacts open. There is 6 ms between the end of the RF output and the relays returning to receive.**

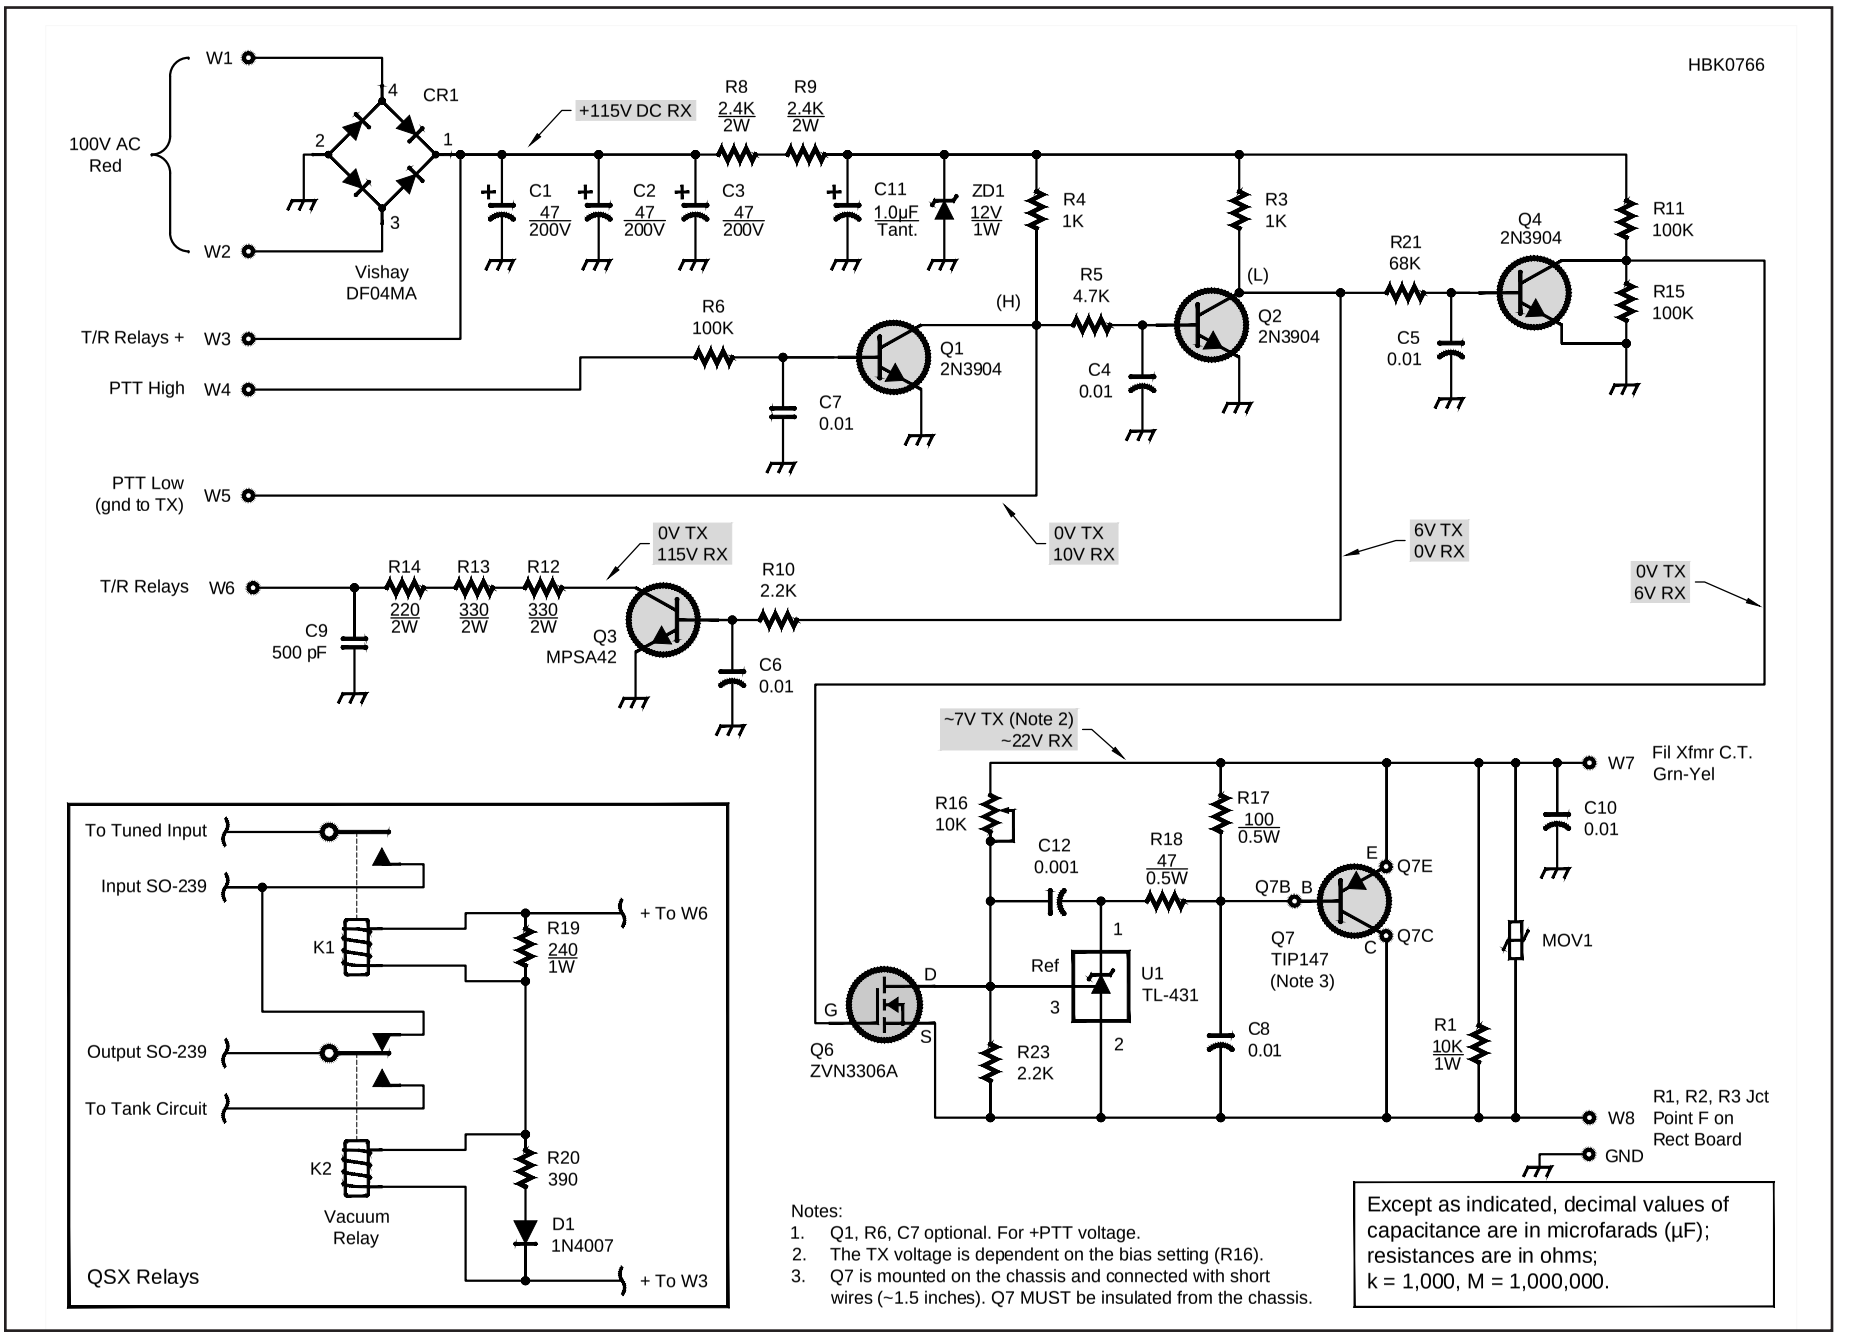

**Figure 71 — The schematic for the SB-220 QSK controller. A PC board layout and parts list may be found with the onine supplemental content.**

applying RF drive before the output of the amplifier was transferred to the antenna system! The Kenwood TL-922 has two huge, slow and loud antenna change-over and bias switching relays. With those s-l-o-w relays, the RF drive was getting to the tubes before the output relay contacts had switched! It was that simple. The Drake had arced in the tuning capacitor at least once. Now, it's smooth as silk. I used my TL-922 with QSK in the 2012 and 2013 ARRL RTTY Roundup contests and it worked perfectly! No arcs or sparks in the entire 30 hour contest on 10, 15 and 20 meters."

Note that properly designed QSK systems prevent hot-switching of the relays and possible arcing in the output tuning network whether full QSK is used or not. This will reduce wear of the relays and stress on the amplifier, leading to more reliable operation.

### Tube Bias Control

In a vacuum tube linear amplifier, the QSK circuit must switch the tube's cathode-to-grid bias from cutoff in receive to a resting-current condition in preparation for transmit at the same rate as the antenna relays. The cutoff bias voltage must achieve the ZSAC (Zero Signal Anode Current, a.k.a. idling current) as stated by the tube manufacturer. For most 3-500Z amplifiers using ~3200 V, this voltage needs to be between 6 and 8 V.

### Components and Construction for QSK

Placement of the relays in the amplifier isn't critical, but installing the relays near the input and output connectors is usually the most convenient and keeps leads short. Relay mounting isn't critical except for keeping them quiet. The author recommends mounting the relay on a rubber grommet through a hole or on a "bed" of silicone glue/sealant. Lead connection has a lot to do with keeping the relays quiet. The shield braid of RG-174 coax works well to absorb vibration. Just make sure you don't get the braid full of solder, or the extra stiffness defeats the purpose. Bend the braid into a fairly large horseshoe shape and solder to the relay terminals, and then solder either to the RF connector directly or to the coax that connects the other circuitry.

Reed relays have glass-encapsulated contacts in a vacuum and a coil wound around the outside of that glass housing. The reed doesn't have to travel very far to make contact so the relay is extremely fast: closing is measured at less than 700 µs (0.7 ms) and opening slightly faster, on the order of 500 µs or less. A contact rating of 1 to 2 A is sufficient for 100 W or less of drive. Because of the speed, relay coil voltage is not critical. A resistor across the coil can compensate for higher or lower coil voltage and current. A 12 V coil reed relay is recommended.

Remember that when the amplifier is turned off or bypassed, the transmitter output RF doesn't pass through the reed relay. You can use a small mechanical relay, but they are slightly slower than a reed relay and are also noisier. Be cautious with the mounting and lead connections to keep the "sounding board" effect to a minimum.

The amplifier output vacuum relay must be of the smaller type such as the Jennings RJ1A, Kilovac HC1, Gigivac GH1, and the generic VHC-1. The Jennings RF1 style is just too slow, as are any of the glass-envelope vacuum relays. Do not use an HC3 or VHC-3 type of relay because they are rated only for dc, not RF.

The RJ1A relay's specified close time is 6 ms. Measurements show a typical closure time of about 3 ms. By using a higher initial voltage, the closure time can be reduced to as little as 1.5 ms, but the average time is around 2 ms.

The relay's release time depends on the relay coil's kickback suppression circuit. The usual circuit is a reversed-biased diode connected across the coil. A resistor in series with the diode dissipates some of the energy in the coil and helps release the relay armature more quickly.

## W7RY — Analog QSK Controllers

This project is really a series of controllers developed by W7RY for several popular non-QSK amplifier models. The SB-220 QSK controller shown in will be summarized as a design example — the schematic is shown in **Figure 71**. Additional construction details for the SB-220 controller are available with the downloadable supplemental content. Design information for the Heathkit SB-200 and the Kenwood TL-922 QSK controllers are also included as separate packages of files.

The goal was to design a board that would be easy to install by anyone with electronics background with little to no support. The other requirement was little to no addition of major components to the amplifier. With the varieties of boards that the author designed, there is probably a board to fit most any amplifier. (See W7RY's web page **www.qrz.com/db/W7RY** for more information on these designs.)

As you may know, some older linear amplifiers used a fairly high voltage to switch the transmit-receive relay(s). Solid-state transceivers then had to use an external relay, which added even more delay to an already slow switching system, or install an aftermarket soft-key module into the amplifier.

The controllers use low voltage switching signals so that no additional power or interface signals are required. There is also a positive voltage input switching line if the available amplifier keying signal is positive-going. Some radios have a very fast positive-going keying signal that is even faster switching than the grounded amplifier relay switching signal. If the amplifier switching relay is a bit slow in your particular transceiver, you might be able to use a positive voltage to key the amplifier.

## W9AC Universal Sequential QSK (S-QSK) Controller

The Universal S-QSK (S-QSK) board (**Figure 72**) is designed to control many RF switching applications, all controlled by an on-board Arduino Nano or PIC microcontroller. Through a choice of microcontroller programs, one S-QSK board can manage many different types of switching functions. Sample code, line-by-line documentation, and structured flowcharts are provided to assist the novice programmer with code customization. Structured logic is used for easy code modification. Copy and paste the source code into the Arduino software's edit window, then upload to the Nano board with a mini USB cable.

Presently, three programs have been written for S-QSK: an amplifier QSK controller; a TR switch for separate receiver-transmitter combinations, and a protection circuit for receiver inputs. (The latter two applications are discussed in the full version of this article with the downloadable supplemental content.) When used as a QSK controller, S-QSK is designed to be used with the user's choice of external RF relays or a PIN diode switch. Circuit boards to support PIN diode TR switching and remote outputs that will interface with S-QSK's headers are being developed by the author.

The schematic of the S-QSK is shown in **Figure 73**. A complete parts list, PCB layout drawings, flow charts, and C++ source code are additionally provided with the downloadable supplemental content. In addition, a double-sided professionally-made PCB is available from the author via his website at **www.qrz.com/db/w9ac**. Updates and revision information will also be made available on the same web page.

A powerful attribute of the Arduino microcontrollers is that they come pre-programmed with a bootloader, allowing the user to quickly upload new C++ code without the use of an external hardware programmer that is commonly needed for PIC and EEPROM chips. Connect a mini-USB cable to a PC USB port and you're ready to program. Optionally, the user can bypass the bootloader and program the microcontroller through the ICSP (In-Circuit Serial Programming) header.

The microcontroller and peripheral circuits

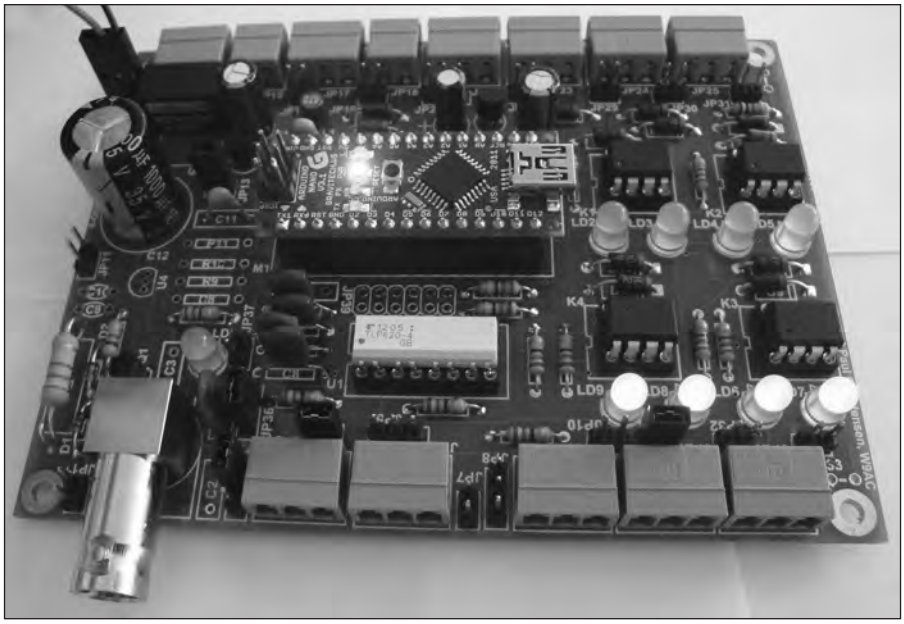

**Figure 72 — The S-QSK board showing the Arduino microprocessor and the LED error indicators. The RF SENSE input connector is at the lower left. [Paul Christensen, W9AC, photo]**

are powered by the USB port during testing, and an external +7 to +12 V supply powers S-QSK during normal operation.

## S-QSK FEATURE SET

A common hardware platform is used to implement many applications where precise timing is required between switching events. The hardware remains the same; only the source code changes for different applications.

- An Arduino Nano or PIC microcontroller plugs into the S-QSK motherboard. Programming a Nano requires no special hardware — code is uploaded via a USB cable from the host PC. For advanced programmers, a 16F88 PIC chip can be used in place of the Nano.
- Uses screw-down Phoenix-style I/O connectors. Each I/O connector can be unplugged from the motherboard for easy assembly and servicing.
- Four digital input channels; eight digital output channels. Header for access to optional analog channels.
- Optically isolated I/O for maximum RFI immunity. Photo-Darlington transistors on the input and solid-state PhotoMOS relays on the output.
- Each input channel can be selected for dry contact closure, fed from a solid-state open collector — or any other solid-state switching device.
- Each output channel can be selected to float or reference circuit ground. Each output can be jumper-selected to function as a current sink or current source.
- RF sampling via BNC connector or 2-pin header. RF is converted to a dc level and conditioned to drive photo-coupler. RF sensing activates with less than 100 mW of RF power.
- Remote RF sensor board can be used to sample RF at a distant location or where a T RF connection presents an unacceptable line mismatch.
- On-board LED diagnostic status indicators on all output lines.
- Uses a +12 V dc-dc converter, bootstrapped to the +12 V supply to provide +24 V for vacuum relays.
- Two optional, jumper-selected relay coil accelerators.
- Board can be populated with only the circuits of interest, thereby saving on construction cost and assembly time.
- Precise control and delay of all steps in 1 ms timing increments.
- Significant hot-switch fault protection built into the code. Before anything can switch between steps, RF is first sampled and judged with the state of the input key line.
- Small board size: S-QSK measures 4.5 × 3.5 inches. The remote RF sensor is 1.7 × 1.6 inches.

## S-QSK OPERATION

S-QSK precisely sequences all critical timing elements between an RF power amplifier and transmitter/transceiver. The S-QSK board will work with QSK and non-QSK amplifiers. A sequenced electronic bias switching (EBS) system is created and supports both two-state and three-state bias control. Switching between types only requires a simple change to the microcontroller code.

The delay time between events is independently adjustable to accommodate various transmitter and amplifier timing characteristics. The input key and RF sensing lines are polled in a loop. Depending on the line states and the state of a flag bit, the S-QSK board's output key line, solid-state relays, and bias control are switched with time sequencing to avoid "hot-switch" effects. (See the flow chart files provided with the source code.)

S-QSK offers hot-switch RF protection by sampling the presence of the complete RF envelope. If RF excitation is present at the input to the S-QSK board before the input key line is active, a switch from receive to transmit is inhibited. Likewise, if the RF envelope has not decayed to zero after transmission, the S-QSK board will not switch back to receive. If either type of timing fault occurs, one of two LEDs will illuminate, showing a fault. The LEDs remain lighted until the timing fault clears. Each LED is pulsed to remain on for 0.5 second in the event of brief timing faults. Upon detection of a post-switch fault, bias lines are deactivated, providing further amplifier protection.

For three-stage EBS systems, "hang" bias is supported and is adjustable by the user from 0 ms to 255 ms in 1 ms increments.

In addition to establishing precise timing between amplifier switching elements, S-QSK can accelerate the relay activation time of frame-type output and input relays. The board contains two optional relay coil accelerators, each powered by a choice of +12 V or +24 V power buses. The accelerator circuits are engaged with header jumpers. For mechanical TR switching, Jennings RJ-1, Kilovac HC-1, and Gigavac GH-1 are all good choices for the RF output relay when they are powered at their rated supply voltage. For the input relay, consider the Aromat/Matsushita RSD-12V.

An RF input sample is capacitively coupled by C1 from the RF SENSE input connector J1 or JP1 header to a detector circuit consisting of R1-R3, C3, D1-D2 and Q1. RF sampling is optically isolated from the microcontroller digital inputs by a photo-transistor in U1. A remote RF sampling board (under development as this edition was being prepared — see the author's website) can also be used in instances where a T RF connection presents an unacceptable line mismatch or where the sample point is at a long distance from the main S-QSK board. The detector circuit will indicate the presence of RF at less than 100 mW of power.

# 17 A Legal-Limit Bias-Tee

The following project by Phil Salas, AD5X, describes a bias-Tee that can be used at full legal-limit power levels from 1.8 to 230 MHz while supplying up to 3 A of dc current. The project was originally published in the January 2013 issue of *QST*. The full article, including all construction details, is available with the downloadable supplemental content. Additional information is available on the author's website at **www.ad5x.com/images/Articles/BiasT3amp.pdf**.

A bias-Tee enables the supply and extraction of dc power via the center conductor of a coaxial transmission line along a high-isolation inductor. It is used to power remotely located RF switches, preamps, and antenna tuners without a separate dc feed. **Figure 74** shows a typical application in which a pair of bias-Tees power a remote antenna tuner.

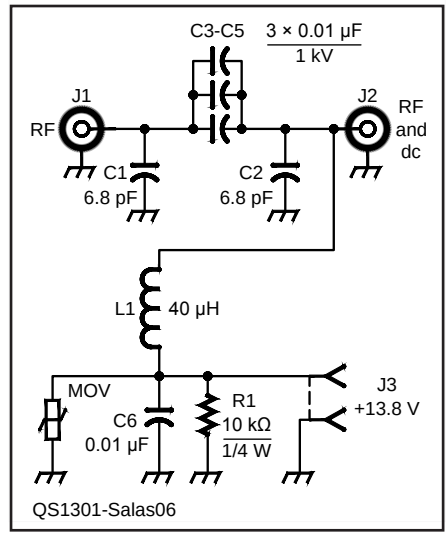

**Figure 75 — Schematic of the bias-Tee. The series 0.01 µF capacitors should be physically large to reduce RF losses. The 40 µH inductor is specifically chosen to present high reactance across the entire operating range (see text).**

## BIAS-T DESIGN CONSIDERATIONS

A dc/RF isolating inductor must provide high reactance across the bands of interest while carrying the required dc current with minimal voltage drop. Also the inductor's Q must be high to minimize power dissipation of the RF signal in the inductor. A large number of inductors were characterized using the author's AIMuhf vector network analyzer. Most had multiple resonances across the HF spectrum or the Q was too low.

The J.W. Miller 5240-RC 40 µH inductor was selected for this design. This inductor is rated to carry 3 A with a typical specified self-resonant frequency of 145 MHz. The choice of inductor is critical to keep impedance high across the entire range of amateur bands through 222 MHz. (The full article with the downloadable supplemental content contains the vector network analyzer data for this inductor and the completed bias-Tee with the 6.8 pF compensation capacitors.)

**Figure 76 — Internal construction of the bias-Tee, following good RF construction practices.**

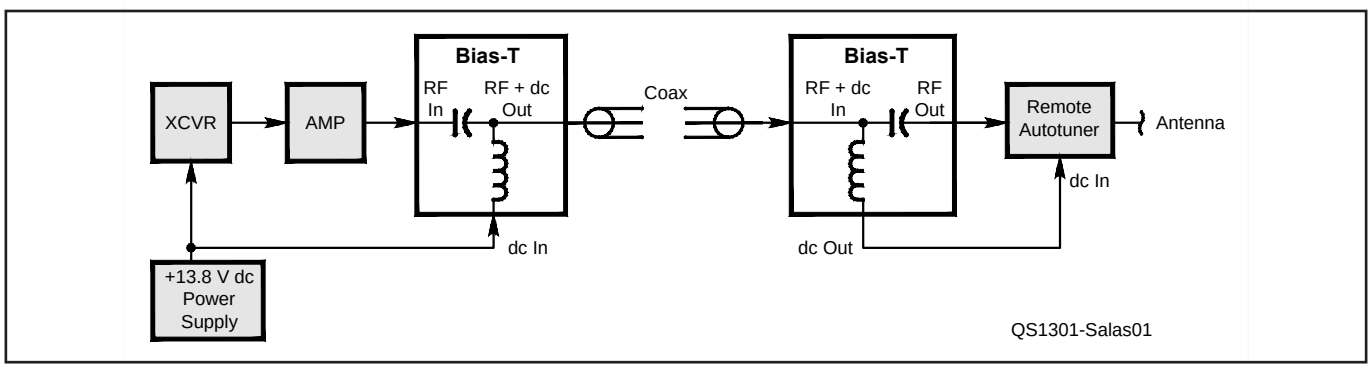

**Figure 74 — Typical application of a bias-Tee in an RF system. The same bias-Tee design is used for supplying and extracting dc power.**

### BIAS-T CONSTRUCTION

**Figure 75** shows the schematic and parts list for the finished unit, including mechanical parts. The bias-Tee was constructed in an inexpensive outdoor electrical cast-aluminum box. **Figure 76** shows the inside of the finished unit. (See the full article with the downloadable supplemental content for a photo of the completely assembled unit and mechanical layout drawings.) A hand-wired assembly like this bias-Tee requires good RF construction practices with direct connections made with short leads if the full range of operation at VHF is to be realized.

All components are mounted on the outlet box cover. The mounting hardware is stainless-steel for outdoor use (the cover includes a weatherproof gasket). The three 0.01 µF, 1 kV parallel capacitors were not chosen for their voltage rating as there should be virtually no RF voltage drop across them. However, physically large capacitors are required to reduce power dissipation from the high RF current through them at legal limit operation (approximately 5.5 A RMS for a 50 Ω load).

In the dc in/out section, an MOV provides transient protection for voltages greater than about 18 V dc and the 0.01 µF capacitor provides RF bypassing. A 10 kΩ resistor provides a dc path to ground — this prevents static buildup when the dc in/out connection is not present or disconnected.

# 18 An Eight-Channel Remote-Control Antenna Switch

(Another remote antenna switch project from previous editions, "A Low-Cost Remote Antenna Switch" by Bill Smith, KO4NR, is included with the downloadable supplemental content.)

This project is a remotely-controlled antenna switch designed by Michael Dzado, ACØHB. It allows the selection of one of eight antennas or can be used to feed one antenna to any of up to eight radios. The complete system consists of a remote switch assembly (shown in **Figure 77**) and a selector control assembly. The switch can be used with a control cable, but any solution that provides logic-level control signals to the switch assembly can also work.

The switch assembly's printed circuit board (PCB) was designed to match 50 Ω feed line and maintain a high port-to-port isolation of 70 dB through 50 MHz. The original article with full construction details and test measurements was published in the March/April 2014 issue of *QEX* magazine and is included as a PDF article with the downloadable supplemental content. Parts lists, PCB layout images, build instructions, kits of parts, ready-to-build PCBs, and additional design details are available from the author at **www.ac0hb.com/RF-Switch_Description**.

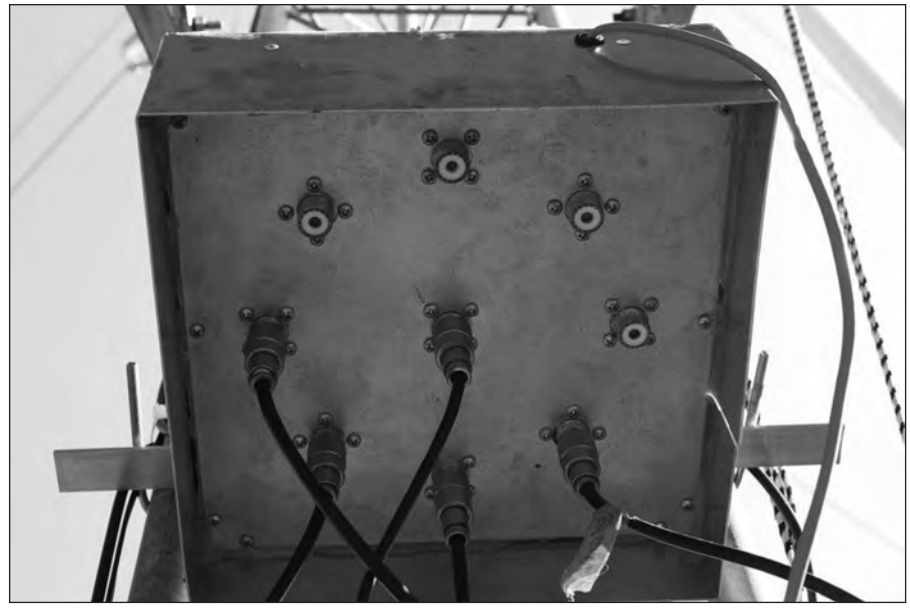

**Figure 77 — The remote antenna selector board mounted on a tower, selecting among four antennas.**

### DESIGN DETAILS

The remote control antenna selector system consists of a remote controller assembly and an RF switch assembly.

The remote controller assembly shown in **Figure 78** was designed as a simple solution for the author's station. The assembly consists of an eight position rotary switch and an 8-to-3 digital encoder connected to 2N2222A transistors that drive the RF switch assembly via a standard CAT-5 eight wire cable.

The RF switch assembly contains the relays and relay drive circuitry to select between

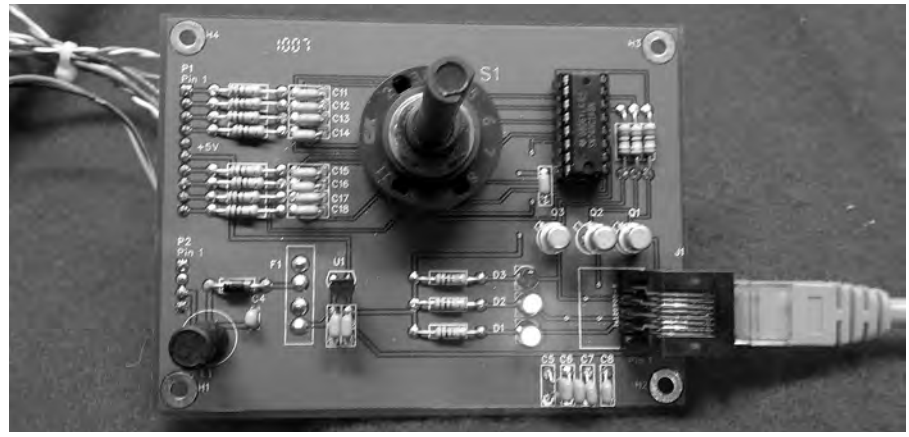

**Figure 78 — The antenna selector system's remote controller printed circuit board.**

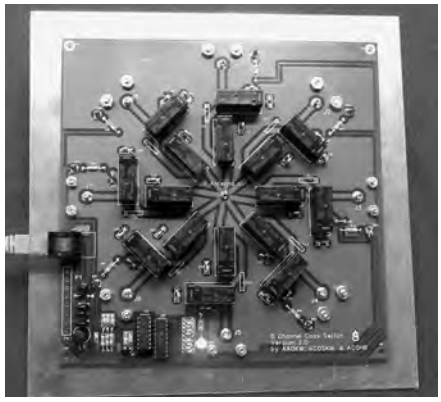

**Figure 79 — The printed circuit board for the antenna switch showing the relays and trace layout. Note the symmetrical layout of the switch.**

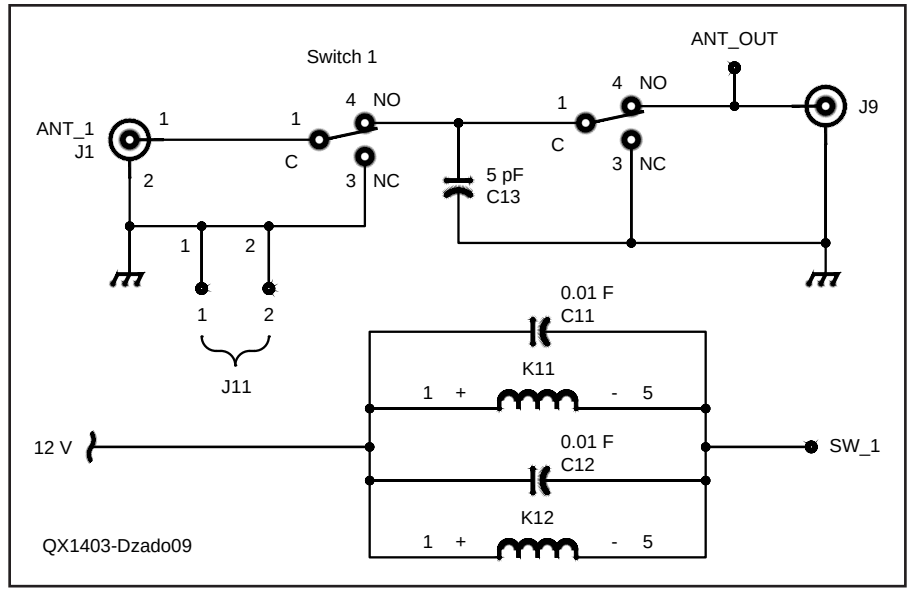

**Figure 80 —The schematic of one section of the antenna switch — this section is repeated eight times. When the antenna is not selected, the normally closed contact of Switch 1 grounds the antenna and the second relay disconnects the common antenna port, J9.**

position 0 to 7. The assembly requires only a 13.8 V dc supply and a 3-bit TTL (digital logic) signal as the input for switch position selection. This interface allows for a variety of remote control solutions. **Figure 79** shows the top view of the assembly. The switch control logic incorporates a simple 3-to-8 decoder (74HC238) and a high current, eight-pair Darlington transistor array (ULM2008A) to provide the relay drive current.

High isolation and impedance matching in the RF switch assembly were achieved through several design techniques: Two relays were used in each signal path to doubly isolate the antenna from the radio input. The traces that make up the RF path were designed as a coplanar waveguide. The RF connector placement on the circuit board was tightly controlled to be symmetrical to make the RF electrical paths identical. RF trace routing followed good design practices by limiting angles to 45°. Control traces were routed on the bottom of the circuit board to maximize ground plane continuity. Control trace widths of 15 mils (0.015 inch) were used for better current capacity.

To minimize RF coupling between antenna channels, it was essential to follow the rules and principles of good basic RF/microwave design. The switch assembly features a coplanar waveguide for all RF traces, designed for 50 Ω impedance with ground plane stitching that ensures maximum isolation between ports. Complete impedance ($Z_0$) matching (50 Ω in to 50 Ω line to 50 Ω out) minimizes return loss and SWR. A coplanar waveguide design was chosen so that the trace impedance on the circuit board could be matched to the input and output impedances. In a coplanar waveguide design, $Z_0$ is a function of signal conductor width and thickness and a function of the dielectric constant ($\varepsilon_r$) of the material surrounding the signal conductors.

Signal return currents follow the path of least impedance. In high frequency circuits this equates to the path of least inductance. Stitching the ground planes with vias every 0.1 inch or so around each RF trace helps minimize the inductance in the signal return path by virtually creating a waveguide on the circuit board.

The RF connectors were placed symmetrically around the output connector (located in the center of the assembly) to ensure an equal electrical length for each RF path. Typical isolation measured between ports is greater than 70 dB.

Extensive RF decoupling on the power and control lines was added to provide maximum RF decoupling from the control signals. Transient-voltage-suppression diodes (Transorbs) were added to all input control lines for good surge protection.

The switching relay is at the heart of this design — an Omron Electronics Inc G6RN-1-DC12, which is a sealed double pole, double throw (DPDT) relay with 8 A silver over gold contacts. The contact capacity is more than adequate for our design. We chose to doubly isolate each RF port by using two relays in each path. As shown in **Figure 80**, the first relay grounds the antenna input when de-energized. The second relay simply disconnects the RF port from the output. This schematic is repeated for each of the eight selectable antennas.

# 19 Digital Audio PTT Interface

This circuit from the November 2016 issue of *QST* was developed by Julian Moss, G4ILO (SK — **www.g4ilo.com**) for digital operation with a computer sound card. It uses the sound card audio output signal to key a transmitter's PTT (push-to-talk) input. A USB audio I/O adapter can also be used to generate the audio output signal.

The circuit in **Figure 81** acts as a VOX (voice-operated transmit) circuit that keys the transceiver PTT input whenever it detects transmit audio from the computer. The circuit also provides an adjustable audio output (C2, R1, and R2) for control of transmit audio level. Q1 and the associated components amplify the input audio, C3, D1, D2, and C4 act as a detector to produce a positive dc voltage when input audio is present. The output of the detector turns on Q2 to key the PTT input. Q1 and DS1 indicate when PTT is active.

The original "Eclectic Technology" column from June 2016 *QST* used an inexpensive external USB audio adapter as the audio connection to the PC. If the PC has direct audio input and output connections, those can be used as shown here. The original article is included with this book's downloadable supplemental information.

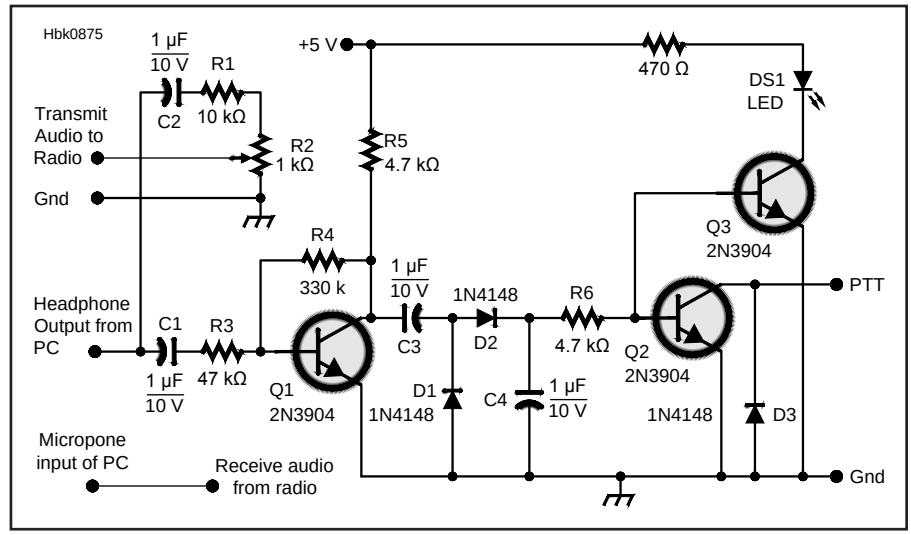

**Figure 81 — The G4ILO digital communications interface provides a PTT signal to a transceiver based on transmit audio from the PC. Transmit audio level is adjustable by the interface. Received audio level from the radio is adjusted by the transceiver's audio gain control. Mouser part numbers shown (www.mouser.com).**

**C1, C2, C3, C4 — 1 µF ceramic disc capacitors (810-FK24X5R1C105K)**
**D1, D2, D3 — 1N4148 diodes (512-1N4148)**
**DS1 — Red LED (78-TLCS5100)**
**Q1, Q2, Q3 — 2N3904 transistors (610-2N3904)**
**R1 — 10 kΩ, ¼ W resistor (791-RC1/4-103JB)**
**R2 — 1 kΩ potentiometer (652-PDB181K415K102A2)**
**R3 — 47 kΩ, ¼ W resistor (791-RC1/4-473JB)**
**R4 — 330 kΩ, ¼ W resistor (791-RC1/4-344JB)**
**R5, R6 — 4.7 kΩ, ¼ W resistors (791-RC1/4-472JB)**
**R7 — 330 Ω, ¼ W resistor (791-RC1/4-331JB)**

# 20 Arduino-Based CW IDer

This project by Bob Anding, AA5OY, was originally published in the January 2017 issue of *QST*. The full article, including programming details, a sketch for the Arduino software, and associated files are included in this book's downloadable supplemental information.

The Arduino microcontroller board is used to generate a CW ID message that is programmable through a PC. The message is initiated by a switch closure which can be mounted on the Arduino assembly or provided by another piece of equipment, such as a timer output. The message content and speed are controlled through the Arduino's sketch software on the host PC.

**Figure 82** shows the schematic of the CW IDer. An Arduino UNO R3 used for this project includes a USB interface for programming via the Arduino's integrated development environment (IDE). The module comes with a Reset button and a number of general-purpose input/output (GPIO) pins.

When the IDer's activation switch (S1) is closed, the timer period starts. The number of seconds in the timed interval can range from 0 to 32,000 seconds. At the end of the interval, the PTT LED and Q1 are turned on. The message is then played back through SP1 as an audio tone. A keying output is easily added through Arduino software or by creating a VOX interface (see the Digital Audio PTT Interface project in this chapter).

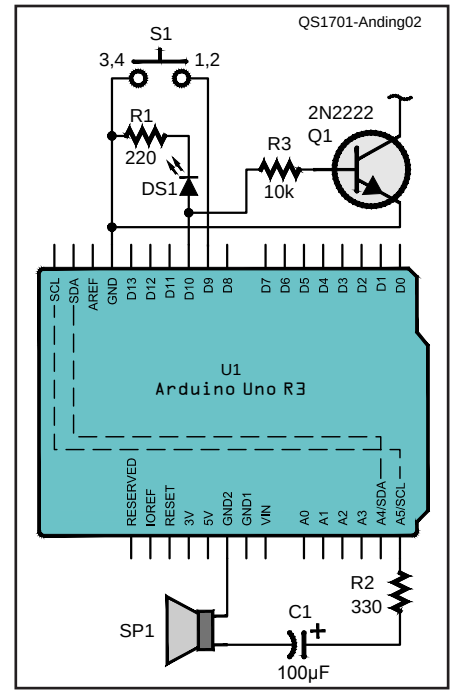

**Figure 82 — The CW IDer uses the Arduino Uno R3 and a handful of parts.**
**C1 — 100 µF, 25 V electrolytic capacitor.**
**DS1 — 5 mm red LED.**
**R1 — 220 Ω, ¼ W resistor.**
**R2 — 330 Ω, ¼ W resistor.**
**R3 — 10 kΩ, ¼ W resistor.**
**S1 — Momentary contact switch (N/O).**

# 2022 HF Transceiver Survey

*By Joel R. Hallas, W1ZR and Mark Wilson, K1RO*

As with most major purchases, there is a wide range of choices among transceivers, ranging from the most basic functionality to more bells and whistles than most operators will ever use. As might be expected, advanced features and performance generally go hand-in-hand with advanced prices.

This Survey considers "all-band" transceivers with 100 W or more output, as well as several low-power all-band models that are intended for portable operation. Although we call them "HF" transceivers, most also cover 160 meters (which is a medium frequency — MF — band). Many also cover 6 meters, some include 2 meters, and a few feature 70 cm and even higher frequency bands. Such wide frequency coverage is a plus for the Technician operators who start out with limited HF privileges in addition to VHF and above, but may upgrade in the future, or for anyone who wants to explore those bands without resorting to multiple radios. All radios discussed here include a general coverage receiver that tunes at least from the AM broadcast band to 30 MHz, so they can also be used for entertainment, shortwave listening, or even spectrum analysis.

The information presented here is current as of early 2021, but products and prices can change dynamically in such a competitive marketplace. Models may be added, updated, or dropped over time and so the lineup available as you read this may have changed. Check dealer and manufacturer web pages, *QST* ads and Product Reviews (reviews from 1980 on are available to ARRL members at **www.arrl.org/product-review**) as you get close to making a choice.

## Categories

Transceivers tend to be grouped into categories based on price points and physical configuration. The price is the typical "street price" — representative of the price they sell for at dealers — not the "list price." Prices were approximate as of early 2021 and are subject to change (up or down). Prices do not include any coupons or limited time promotions. Check with your favorite dealer (or manufacturer for those who sell direct) for current pricing — it will be different from the representative pricing shown in the tables. The categories break down as follows:

*Entry-level, Portable and Mobile* — Desktop transceivers that cost up to about $1000, and radios that have 100 W output and are often favored by portable and mobile operators.

*Mid-range* — Desktop transceivers that cost around $1000 to $2500.

*Upper mid-range* — Desktop transceivers that cost around $2500 to $4000.

*Top-level* — Transceivers costing $4000 and up.

*Low-Power Portable* — Radios that are intended for portable operation and typically offer up to 15 W output, cover all of the HF bands, and operate SSB, CW, and digital modes. Some also have VHF/UHF coverage and FM/AM operation.

Unless otherwise noted, the 100 W radios described are designed to operate from a nominal 13.8 V dc power supply, usually at around 20 to 22 A. The radios at higher power levels tend to have special power supply configurations, often requiring operation from ac mains. Most manufacturers offer a 13.8 V "matching" power supply for the 100 W radios. Aftermarket general purpose power supplies meeting the radio's specifications may also be used.

One of the most active areas of transceiver development is in the application of digital signal processing (DSP) and software-defined radios (SDR). It is worth continuing to educate yourself on these capabilities, as they are displacing a significant number of analog technologies.

Obviously, the assignment of a transceiver to a particular class is somewhat arbitrary and depends on personal tastes and operating requirements. Take the following lists as general assessments and don't be afraid to make your own rankings! In addition, new models and features are continuously introduced. Watch for products announced or reviewed in *QST* and on the manufacturer and dealer websites.

## Features of Current Transceivers

Current 100 W (or higher) transceivers tend to include the following features. Some features tend to appear in transceivers of different price ranges, thus the features have been placed in generic groups based generally on price class.

### BASIC FEATURES

The following basic features are shared across every category of transceivers. The following is not an exhaustive list but should provide an indication of the benefits of some of the more popular features.

- *A general coverage receiver* — Typical coverage is from below the medium-wave broadcast band (sometimes lower with reduced sensitivity) to the top of HF, sometimes well into VHF, depending on trans-

ceiver frequency coverage. This is also useful to allow listening to international broadcast stations or other services, as well as the 630- and 2200-meter amateur bands. It is also very useful as an adjunct to an amateur's workbench as a test instrument.

• *Wide transmit frequency coverage* — All current models extend downward to MF (160 meters) and most extend into VHF with coverage through 6 meters. Some go further into VHF and even UHF, or offer low-level outputs on 630 and 2200 meters. In some cases the additional coverage may reduce or eliminate the need for one or more additional radios in the station, making for a more compact, and sometimes less expensive, station.

• *Multiple modes of operation* — Most current transceivers offer SSB, CW, AM, and FM modulation and detection. Most offer provision for digital modes, and some have built-in decoders and encoders for PSK or RTTY operation. Depending on frequency coverage, some "HF+" transceivers can also serve as VHF FM transceivers, offering standard repeater frequency offsets, squelch, and tone encoding.

• *Choices of selectivity* — Current generation transceivers offer DSP-based variable selectivity (filters), although a small number of older designs still on the market may still rely on crystal filters. In lower-cost models, DSP filtering tends to be a small but usually adequate number of discrete choices, while in higher priced units selectivity is often continuously variable in 50 or 100 Hz steps. Advanced units allow shaping of the passband as well as high- and low-frequency rolloff adjustment. Some offer a dual-passband filter, designed to separately pass each tone of an FSK (radioteletype) signal and not the frequencies between them, thus improving the detection probability in noise or interference.

• *Dual VFO operation* — All current designs offer instant selection of either of two operating frequencies to facilitate split-frequency operation. This allows the setting of one frequency for transmit and another for receive. A single switch or button can be used to toggle between the two so that the transmit frequency can be monitored before transmitting.

• *DSP impulse noise and automatic notch filtering* — Most DSP-equipped transceivers provide for the reduction of impulse noise, such as that from ignition systems or power lines, as well as the elimination of steady interfering carriers.

• *CW keyer* — Most current model transceivers include the capability to connect keyer paddles for sending CW via an internal keyer. Some also include memories to allow one-button transmission of short messages.

• *Removable front panel* — Transceivers designed for mobile operation often have a removable front panel. This allows a compact control head to be mounted near the operator, while the radio's main chassis can be located in the trunk or other out-of-the-way spot.

## FEATURES FOUND IN ADVANCED TRANSCEIVERS

More advanced transceivers tend to have additional features for their increased price. Most are larger than the basic units so that the front panels can accommodate additional controls and displays to support the extra features.

• *Multiple roofing filter bandwidths* — Most basic transceivers incorporate a single roofing filter with sufficient width to permit use on all modes. A typical value is 15 to 20 kHz. Improved close-in dynamic range performance for narrower bandwidth modes, such as SSB, CW, and data modes, can be obtained by having narrower roofing filters available to match the transmit bandwidth.

• *Adjustable noise blanking* — Some transceivers include a separate wideband receive channel designed to detect and blank the main receiver in the presence of impulse noise. This capability is often independent of the similar DSP-based function. One or the other may be found to be better at eliminating noise from particular sources, while sometimes using both is even more helpful. Some transceivers offer two separate methods of noise blanking, each suited for different common types of impulse noise.

• *Choices of AGC parameters* — Most transceivers provide automatic AGC settings for different operating modes. Some advanced transceivers provide additional choices to allow optimization for different kinds of operation and different ambient noise levels. For example, to maximize sensitivity for weak signals, the AGC operating threshold should generally be set above the external noise level. This will vary depending on ionospheric conditions. Other parameters include the slope of the AGC curve and hold and attack times.

• *Frequency memories* — Advanced (and some basic) transceivers include the capability to store operating frequencies and other settings in memory. "Band-stacking registers" are multiple memories for each band that are typically accessed by pressing the band selection button multiple times. Typically they will store two or three frequencies per band, along with mode, filter and other settings, in a last-in, first-out register stack.

• *Dual receive* — Some higher-end transceivers include two independent receive channels. Dual receive channels can be useful to monitor two frequencies simultaneously. For example, you could listen simultaneously to transmit and receive frequencies being used by a DX station operating in split mode.

There are some subtle differences between the *sub-receiver* capabilities of different model transceivers. In some transceivers, the sub-receiver can only be used in the same band as the main receiver. This is not a limitation for normal split operation, but it does not permit monitoring a different band for openings or other activity. While some transceivers offer a duplicate receiver system for the sub-receiver, others have sub-receivers with lower dynamic range performance or fewer filter options than the main receiver.

Some sub-receivers have independent antenna input connections that allow operation with two different antennas. If the tuning of the two receivers can be locked together, that can provide a kind of diversity operation to reduce effects of fading. Typically that might entail polarization diversity (one horizontal antenna, one vertical); space diversity with two antennas separated by a wavelength or so; or arrival angle diversity, using horizontal antennas at different heights.

• *Panadapter* — While a visual view of the received spectrum has been possible for decades with a station accessory called a *panadapter*, these devices were not too common in amateur stations until manufacturers started building display screens into transceivers. Many current transceivers offer panadapters in different forms. Often they offer views of signals on a band, adjustable over a range from the immediate vicinity of the operating frequency to the whole band.

The display may be a conventional spectrum analyzer-style display with signal displayed as individual peaks, although *waterfall* displays are becoming more popular. In a waterfall display, signal strength is displayed as intensity or color on sequential frequency range scans. A recent trend is the inclusion of both a panadapter and a waterfall view, in a *panafall* display. See the **Transceiver Design Topics** chapter in the *ARRL Handbook* for more about panadapter and waterfall display systems.

Some transceivers with dual receivers provide either dual panadapters or the ability to use one on the second receiver to keep track of band openings while communicating on the main band. In some cases, the receive circuitry is shared with the panadapter so that the audio is disabled during the time of the scan.

A *real-time* panadapter scans the frequency segment and repeats the scan over

and over, giving an appearance of continuous updates. Thus newly arrived signals will show up during each scan. Some panadapters offer a single-pass or *one-shot* functionality in which a button press initiates a single scan over the selected range. The display retains the same snapshot of band activity until the next time the button is depressed. While this can provide a sample of band activity, it does not provide the same level of information as a real-time display.

Some transceivers provide a wideband IF output ahead of roofing filters so that an external panadapter can be used to monitor the received band. The wideband IF output can be used by other external signal processing equipment as well.

• *Higher power* — Transceivers are available at many output power levels, from the very compact and portable low power (QRP) transceivers to medium power radios. While the usual 100 W PEP output transceivers are the most popular, some transceivers provide up to 200 W PEP output or more. SDR transceivers with output power of 10 to 50 W PEP are becoming more common. These transceivers require an external RF power amplifier to reach the 100-150 W level.

• *Audio equalization* — Long a capability of amateurs interested in broadcast-quality voice signals, many newer transceivers provide a DSP-based audio equalization capability similar to professional studio control consoles. This is often available in both transmit and receive. In receive mode, it functions largely as a higher resolution tone control. In transmit mode, equalization can be used to shape audio response to provide higher fidelity. Or it can be used to focus the response to best punch through a DX pileup or compensate for individual voice or microphone response.

• *Memory voice recorder* — Sometimes called a *voice keyer* because of the similarity to a CW memory keyer, this function allows you to record and play back short messages. Voice keyers use digital technology and store the voice signal into memory. Different radios have different numbers of such memories, and some also can record received audio for playback on the air or to record a contact.

• *RTTY and PSK31 decode* — Some transceivers include the capability to decode RTTY and PSK31 transmissions directly on the display screen, eliminating the need for a separate PC and sound card. There usually is a limited amount of screen space for decoded messages, but it is usually plenty for contest exchanges or occasional contacts. A few transceivers provide connections for a computer keyboard to allow sending without an attached PC.

# Entry Level, Portable, and Mobile Transceivers

Entry-level, portable, and mobile transceivers available as of early 2021 are shown in **Table 1**. The entry-level IC-718 has been around for a while, so it doesn't have all the latest digital technology or cover 60 or 6 meters, but it does offer a nice set of basic features. The operating bandwidth is set via discrete physical filters. A 6 kHz filter for AM and a 2.4 kHz filter for SSB are provided. A single additional slot is provided for an optional filter such as a narrow CW filter. The IC-718 does not include an antenna tuner, but compatible external tuners are available from Icom and others. This radio includes an audio DSP add-on module that offers digital noise reduction and a digital notch filter. If you need to add optional features such an antenna tuner and CW filter, the price will go up considerably, bringing it more in line with, or even higher than, some of the other choices.

The popular portable/mobile radios in Table 1 (IC-7100, FT-891, FT-991A) are 100 W HF transceivers that usually include one or more VHF/UHF bands (low-power portable transceivers are shown in a later section). They have many of the features of larger radios, but they are compact and designed for the tight cockpit of modern vehicles, or for easy transportation to a portable location.

There is no reason these radios can't be operated from a home station as well. The usual trade-off is that they have smaller front

**Table 1**
**Transceivers in the Entry Level and Portable/Mobile Categories**

All are 100 W PEP output transceivers unless otherwise noted.

| *Model* | *Street Price* | *DSP* | *60 Meters* | *V/UHF* | *Ant Tuner* |
|---|---|---|---|---|---|
| Icom IC-718‡ | $600 | NB, NF | No | No | No |
| Icom IC-7100* | $999 | IF | Yes | 6, 2 m; 70 cm | No |
| Yaesu FT-891 | $640 | IF | Yes | 6 | No |
| Yaesu FT-991A‡* | $1250 | IF | Yes | 6, 2 m; 70 cm | Yes |

‡Single unit radio, others have separable control head.
* IC-7100 is 50 W output on 2 meters, 35 W on 70 cm; FT-991A is 50 W output on 2 m and 70 cm.

**Icom IC-718**

panels with fewer and smaller controls. They often make up for the missing controls with more programmable menus that some operators may find cumbersome. Still, they may be perfect for a compact home radio station, and can be moved to a vehicle as needed.

Note that the IC-7100 and FT-891 have a removable front panel that is designed to be mounted in the front of a vehicle, while the body of the radio can be mounted in the rear or under a seat. All can be combined together in some way to operate as a single unit for home or field use.

The Icom IC-7100 has a separate front panel that is a bit different from others. It's set at an angle and can be easily viewed if used on a tabletop, or in some mobile arrangements. It also can be operated via touch screen, as well as via the usual controls.

**Icom IC-7100**

---

The compact Yaesu FT-891 is an HF-focused radio, supporting 160 – 6 meter operation with CW, AM, and SSB modes and DSP processing. Yaesu's FT-991A is well into the Mid-range price category but with many advanced features, including dual roofing filters, a full-time spectrum scope, and a touch-screen display.

Some of these radios can operate into the VHF and UHF range. Not only do most operate FM there, but they can also operate SSB, CW and even AM, making them much more versatile than the usual VHF FM-only mobile setup. Some will even allow reception of wideband FM broadcast signals, but none will likely be confused with a high fidelity audio system.

**Yaesu FT-991A**

**Yaesu FT-891**

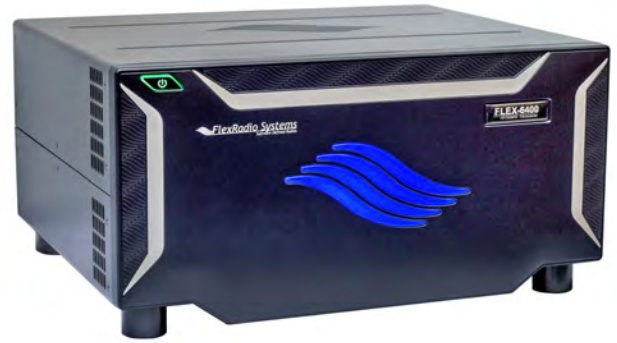
# Mid-Range Transceivers

What do you get if you dig a bit deeper into the checkbook, say $1000 to $2500? Generally, you get a somewhat larger radio with easier to grasp controls, more features — or more choices within a feature type, such as more operating bandwidths to choose from. In some cases, you get a colorful display screen that includes a panadapter. All are relatively recent designs with IF DSP, allowing a wide range of operating bandwidths.

You also may get better receiver performance — perhaps one of the key elements that separate the radios at the higher price ranges. In this case we are talking about the ability to receive a weak signal within a kHz or two of a strong one — *close-in dynamic range*. The higher the number the better, and as noted there is quite a range. While this is only one of the many parameters evaluated in the ARRL Lab during the review process, some believe it is the key in a crowded operating environment such as contesting or DX chasing. When the band is crowded with very strong signals operating nearby, you can experience interference *generated in your receiver* caused by mixing products from those nearby signals or from reciprocal mixing noise from your frequency synthesizer. The higher the close-in dynamic range, the less likely you are to experience internally generated interference to stations you are trying to hear.

There are three primary dynamic range limitations tested during ARRL Product Review testing: blocking gain compression dynamic range, intermodulation distortion dynamic range, and reciprocal mixing dynamic range. Since any of the three can be the limiting factor in dynamic range, the lowest is shown as "Min DR" in the tables for mid and upper-range transceivers, with the lowest dynamic range noted by BG for blocking, IM for intermodulation and RM for reciprocal mixing dynamic range.

Another consideration is transmitter linearity and dynamic range. Having an excellent receiver performance can be circumvented by having nearby transmitters with wide signals caused by various mechanisms in both CW and SSB modes. These factors are not reported here, but are shown in *QST* Product Reviews. For SSB, look for the level of intermodulation products and for CW, the keying sidebands. The same frequency synthesizer phase noise that limits reciprocal mixing dynamic range on receive will result in wideband transmit signals as well. The best transceivers have good characteristics in both receive and transmit.



We have summarized some of the key features and parameters of Mid-range transceivers in **Table 2**.

**Table 2**
**Transceivers in the Mid-Range Category**
Street price $1000 to $2500
All are 100 W transceivers.

| *Model* | *Street Price* | *DSP* | *60 Meters* | *V/UHF* | *Ant Tuner* | *Min DR (dB) (2 kHz)* |
|---|---|---|---|---|---|---|
| FlexRadio FLEX-6400* | $1999 | RF | Yes | 6 m | $299 | IM 94** |
| Icom IC-7300 | $1100 | RF | Yes | 6 Meters | Yes | IM 95 |
| Kenwood TS-590SG | $1400 | IF | Yes | 6 Meters | Yes | RM 94†† |
| Yaesu FTDX10 | $1700 | IF | Yes | 6 Meters | Yes | IM 108 |

*Requires a PC for operation.
**FLEX-6400M version tested.
††Downconverting bands: 160, 80, 40, 20 and 15 meters. DR is generally less on the upconverting bands — 60, 30, 17, 12, 10 and 6 meters — as well as general coverage.

The FlexRadio Systems FLEX-6400 is a direct-sampling SDR with excellent performance and a wide range of features normally found in higher-priced radios. The SDR has no front panel controls, but can be operated from companion *SmartSDR* software running on a PC, iOS device, or optional Maestro control head.

**FlexRadio Systems FLEX-6400**

The Icom IC-7300 uses direct-sampling SDR architecture in a conventional-looking HF transceiver package. It features good receiver and transmitter performance, a colorful display screen, and built-in antenna tuner.

**Icom IC-7300**

The Kenwood TS-590SG is a compact transceiver with a high performance down converting receive capability on some bands (see Table 2 for details) and a very clean transmitter. It has fully adjustable DSP bandwidth filtering, transmit and receive equalizers, provision for a separate receive antenna, and many other features.

**Kenwood TS-590SG**

The Yaesu FTDX10 is a lower priced, 100 W, single receiver version of the Top-range FTDX101D. It includes a colorful display screen and is highly configurable through a menu system, a very good performing receiver, clean transmitter and other features found on high-end radios. Yaesu's FT-991A falls in this price category and was discussed in the Portable/Mobile section. It is popular with home-station operators as well.

**Yaesu FTDX10**

# Upper Mid-Range Transceivers

Transceivers in the upper mid-range group from $2500 to $4000 offer a number of choices between different desirable features. Key parameters are noted in **Table 3**. Some offer more or different features, while others make a push toward higher performance. At the top of the next bracket, manufacturers try to provide everything, while here you need to look carefully and decide what is most important.

**Table 3**
**Transceivers in the Upper Mid-Range Category**
Street price $2500 to $4000
All are 100 W transceivers except FTDX5000MP (200 W).

| *Model* | *Street Price* | *2nd Rcvr* | *V/UHF* | *Ant Tuner* | *Min DR (dB) (2 kHz)* |
|---|---|---|---|---|---|
| Apache ANAN-7000DLE* | $2795** | Yes | 6 Meters | No | IM104 |
| FlexRadio FLEX-6400M | $2999 | Yes | 6 Meters | $299 | IM 94 |

| Icom IC-7610 | $3000 | Yes | 6 Meters | Yes | IM 101 |
| Kenwood TS-890S | $3900 | No | 6 Meters | Yes | IM 104 |
| Yaesu FTDX5000MP | $3800 | Yes | 6 Meters | Yes | RM 104 |
| Yaesu FTDX101D | $3300 | Yes | 6 Meters | Yes | IM 110 |

*Requires a PC for operation.
**MKII version. Versions with internal computer available at additional cost.
††FLEX-6600M version tested.

The ANAN-7000DLE MKII is a 100 W transceiver that offers multiple receivers and and a Pure Signal function that reduces transmitted IMD products. The base model requires a PC or optional PiHPSDR controller for operation, but two higher priced models that include an internal PC are available. These models require just a keyboard, mouse, and monitor for operation.

**Apache Labs ANAN 7000DLE MKII**

FlexRadio Systems has two models in this price category. The FLEX-6400M is like the FLEX-6400 in the previous category, but is packaged in a box with a front panel display and controls similar to a traditional transceiver. It can also be operated locally or remotely from a PC, iOS device, or Maestro controller. The FLEX-6600 is a step up in performance from the FLEX-6400 series. It's capable of full SO2R (single operator, two radio) operation, and can even be used by two operators at the same time. The FLEX-6600 in this category requires a PC, iOS device, or Maestro controller for operation, while the FLEX-6600M in the next category has an integrated display and controls.

**FlexRadio Systems FLEX-6400M**

The Icom IC-7610 direct-sampling SDR builds on the technology of the IC-7300. The key step up from the '7300 is the addition of a completely independent second receiver, with performance equal to the primary receiver and separate audio channels for speakers or headphones. In addition, the dual frequency readouts and virtual analog multimeters are reminiscent of the larger, heavier, and more expensive IC-7851 front panel.

**Icom IC-7610**

Kenwood's TS-890S has a single top performing down conversion receiver with multiple roofing filters and a very clean transmitter. The colorful display features direct sampling band scope and provision for RTTY, PSK, and CW decoding and transmission. It can be remotely controlled, and interconnected with a TS-590SG as a separate receiver.

**Kenwood TS-890S**

The Yaesu FTDX5000MP offers a precise master oscillator and a 300 Hz roofing filter as well as a 200 W PEP transmitter.

Yaesu's FTDX101D is a downconverting SDR that uses roofing filters for excellent receiver dynamic range. It features a very clean synthesizer and excellent transmitter performance as well. A 200 W version, the FTDX101MP, is shown in the Top-range category.

**Yaesu FTDX101D**

# Top-Range Transceivers

Transceivers at the very top of the price range (**Table 4**) are available from a number of manufacturers. These transceivers span a considerable variation of prices, but at more than $4000, it probably doesn't make too much sense to subdivide the list. Buying decisions are driven by subtle differences in features or the desire for optimum receiver performance, a key issue with many contest and DX-focused operators.

The previously discussed Elecraft K3S epitomizes flexibility through its extensive options list, as well as top-shelf receiver performance. The version priced in Table 4 is the Contester/DXer package, with autotuner, digital voice recorder, second receiver, a selection of roofing filters for both receivers, and P3 panadapter.

**FlexRadio Systems FLEX-6600M**

The FLEX-6600M from FlexRadio Systems is the self-contained version of the FLEX-6600 discussed in the previous category. Another SDR transceiver from FlexRadio is in this category is the FLEX-6700 offers advanced features including eight simultaneous receive and display channels. It requires companion software running on a PC, iOS device, or Maestro controller for operation.

**FlexRadio Systems FLEX-6700**

**Table 4**
**Transceivers in the Top-Range Category**
Street price more than $4000

| *Model* | *Street Price* | *2nd Rcvr* | *Power* | *V/UHF* | *Ant Tuner* | *Min DR (dB) (2 kHz)* |
|---|---|---|---|---|---|---|
| FlexRadio FLEX-6600M | $4999 | Yes | 100 W | 6 Meters | Yes | IM 104 |
| FlexRadio FLEX-6700† | $6999 | Yes | 100 W | 6 Meters | Yes | IM 92 |
| Icom IC-7851 | $12,500 | Yes | 200 W | 6 Meters | Yes | IM 105 |
| Kenwood TS-990S | $7300 | Yes | 200 W | 6 Meters | Yes | RM 87 |
| Yaesu FTDX101D | $4200 | Yes | 200 W | 6 Meters | Yes | IM 110 |

†Requires a PC for operation.

At Icom's top end, the IC-7851 features two high-performance receivers, a low-noise synthesizer, flexible panadapter, and a host of other high-end features.

**Icom IC-7851**

Kenwood's Top-range TS-990S offers two independent high performance receivers, a spectrum scope, and many other features. It has a 200 W transmitter and built-in power supply.

**Kenwood TS-990S**

Yaesu's FTDX101MP has a receiver architecture and excellent performance similar to the FTDX101D described earlier. It adds a standard 300 Hz roofing filter and a MicroTune preselector unit for the second receiver. The radio features a 200 W transmitter and includes a companion power supply with integrated speaker. Like the FTDX101D, it has a very clean synthesizer and excellent transmitter performance.

**Yaesu's top-tier FTDX101MP**

# Portable Low-Power All-Band Transceivers

With the increasing interest in portable operation, a number of small, battery-friendly transceivers have hit the market. The radios listed in **Table 5** can have up to 20 W output, cover 80 – 10 meters (and sometimes 160 and 6 meters), and operate on SSB, CW, and data modes. Some include AM and FM voice operation as well.

The CommRadio CTX-10 is an SDR with display and hardware controls that is built in a rugged case. It covers 80 – 10 meters and is designed for low power consumption. It has a built-in battery.

**CommRadio CTX-10**

Elecraft offers two low powered portable transceivers, the KX2 (10 W) and KX3 (15 W). The KX2 offers HF operation only in a very compact package. The somewhat larger KX3 adds 160 and 6 meter coverage and has room for an optional internal 2-meter transverter. Both radios are available with a range of options such as integrated CW paddles and antenna tuners.

**Elecraft KX3**

**Elecraft KX2**

The Icom IC-705 is a 10 W (5 W with internal battery) SDR that covers 160 through 10 meters, plus 6 and 2 meters and 70 centimeters. Its color touchscreen is similar to the desktop IC-7300, and it shares many features with that radio. It operates on D-STAR as well as SSB, CW, AM, FM and digital modes.

**Icom IC-705**

The Lab599 TX-500 is a rugged SDR designed for portable operation with low power consumption. It has a 10 W transmitter and operates from 160 – 6 meters, SSB, CW, AM, FM and digital modes.

**LAB599 TX-500**

**Table 5**
**Portable Low-Power, All-Band HF Transceivers**

| *Model* | *Street Price* | *Power* | *V/UHF* | *Min DR (2 kHz)* |
|---|---|---|---|---|
| CommRadio CTX-10 | $1000 | 0 – 10 W | No | 58 dB |
| Elecraft KX3F | $1250* | 0 – 15 W | 6 Meters (2 m avail) | 100 dB |
| Elecraft KX2 | $900* | 0 – 10 W | No | 87 dB |
| Icom IC-705 | $1200 | 0 – 10 W | 6 & 2 Meters, 70 cm | 90 dB |
| Lab599 TX-500 | $900 | 1 – 10 W | 6 Meters | 82 dB |
| Xiegu G90 | $450 | 0 – 20 W | No | 84 dB |
| Xiegu X5105 | $500 | 0 – 5 W | 6 Meters | 58 dB |
| Yaesu FT-818 | $700 | 0.5 – 6 W | 6 & 2 Meters, 70 cm | 62 dB |

*Factory wired. Other options available.

The Xiegu X5105 covers 160 – 6 meters with a 5 W transmitter. It has many features found on larger radios, including a built-in antenna tuner and general coverage receiver. Xiegu also offers the G90, a 20-W portable SDR transceiver that covers 80 – 10 meters with many features found on desktop radios. This radio has a color display, spectrum scope, and other useful features.

Xiegu G90

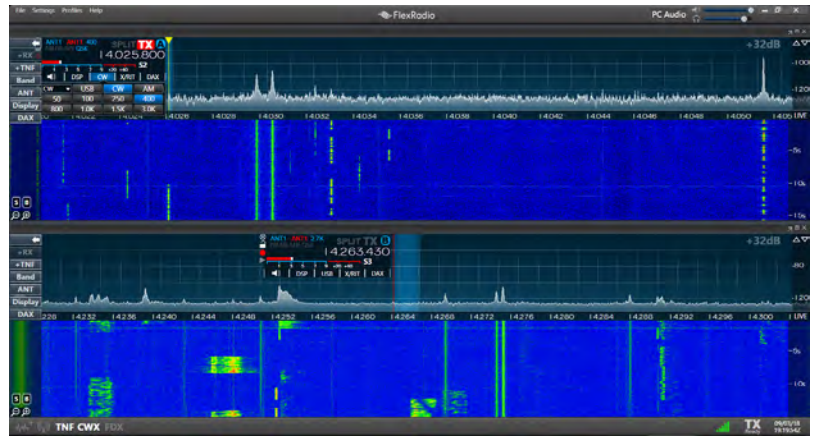
Xiegu X5105

Yaesu's FT-818 builds on the popular FT-817. This micro-size 5 W SSB, CW, data, and FM transceiver covers the 1.8 – 440 MHz bands (excluding 222 MHz) and is popular with VHF/UHF hilltoppers and satellite operators.

Yaesu FT-818

# Software Defined Radios

We described some HF transceiver choices as "software-defined radios" or SDR. It may be worth a short digression to discuss this topic in the context of available equipment. Software-defined radio architecture and design is covered in more detail in the **DSP and SDR Fundamentals** and the **Receiving** chapters.



In the amateur environment, we are particularly interested in radios that can be changed through software by the end user or operator to meet their needs or to take advantages of newly developed capabilities.

The ideal SDR would thus have a minimum of physical constraints. On the receive side, the antenna would be connected to an analog-to-digital converter that would sample the entire radio spectrum. The digitized signal would enter a processor that could be programmed to analyze and decode any form of modulation or encoding and present the result as sights and sounds on the output side of the processor.

On the transmit side, the processor would accept any form of information content, convert to digital if needed, process it into a waveform for transmission and send out a complex waveform conveying the information as an RF signal on the appropriate frequency or frequencies, at the desired power level to transmit from the antenna.

While in the past, our utopian SDR was much easier to imagine than to construct, several amateur radio manufacturers have introduced transceivers that are implementations of this principle in a package that looks and feels like a typical transceiver. Other SDRs use the "blank front panel" approach that requires a separate PC or hardware controller for operation.

The key to amateur SDR operation with a PC remains the analog-to-digital conversion process. This is the point at which the analog RF signals are digitized for processing. Early and more basic SDRs made use of a computer's sound card, or sometimes an external interface device, to perform this function. The newest high performance SDR transceivers no longer depend on the PC for the A/D conversion process, instead using high-speed processors within the SDR platform itself. The PC is now primarily used for the control and display functions with the "heavy lifting" happening in dedicated circuitry within the SDR.

**One version of the main operating screen of *SmartSDR for Windows* operating software for the FLEX-6000 series transceivers. In this case a FLEX-6400 has two receivers with spectrum scopes going simultaneously.**

## THE "BLANK FRONT PANEL" ARCHITECTURE

The best known amateur transceivers of this type are several generations of transceivers from FlexRadio Systems, which started with the SDR-1000, reviewed in *QST* in 2005. The product line has matured, and the current generation is a family of SDR systems called the FlexRadio Signature Series. The FLEX-6400, FLEX-6600, and FLEX-6700 appear in the tables. The front panel has no controls and all control functions are implemented by soft buttons on the software's computer screen. (*SmartSDR for Windows* or for iOS devices is used with the FlexRadio 6000 series radios.) FlexRadio also offers an optional FlexControl USB tuning knob that connects to the computer and the Maestro, a feature-laden control head that avoids the need for a connected PC.

Other SDR transceivers operate with open source software freely available under the GNU Public License. These include the SDR transceivers from Apache Labs such as the ANAN 7000DLE shown in the tables. There are also a number of very low cost SDRs available from various vendors. (Source code for software called "open source" can be viewed and modified. Thus, not only can you upgrade the radio, but also change functionality to make the radio do what you want.)

## THE "LOOKS LIKE A RADIO" APPROACH

More and more current radios are SDRs that are built in a traditional case with front panel displays and controls. These radios look like most any other pre-SDR radio in that they have front panels with knobs and dials and displays. While all radios in this group are designed primarily to operate without an external computer, they all can be computer controlled with typical logging or station management programs, and they can also be controlled remotely.

## DIFFERENCES IN PERFORMANCE

Although at one time SDRs gave up some performance to traditional transceiver designs, that's no longer the case. There are top-performing SDRs available in Mid-range, Upper Mid-range, and Top-range categories.

There will always be some who prefer the more traditional radios and are happy to have it configured and to let it stay the way they like it. Others, especially those who enjoy computers as well as radios, will prefer a transceiver that might undergo continuous improvement as software and firmware are refined and improved. What's really nice is that we can go whichever direction we choose!

## Making a Selection

You know the facts — how can you choose? Looking at tables and product reviews (all *QST* Product Reviews since 1980 are provided to ARRL members online at **www.arrl.org/product-review**) provides a great start, but just as with finding the perfect life partner, the numbers don't tell it all. With radios there's also an element of love at first sight, tempered by the way the radio feels to you as you operate it — ergonomics.

Each manufacturer has a different philosophy for structuring the controls and menus, and you may find a great preference for one person-to-machine interface over another. The *QST* Product Reviews attempt to capture some of the subjective impressions, at least as seen through the eyes of the reviewer.

If you have an opportunity, try out the radios you are thinking of buying. If you are in a local club, find out who uses radios that you are considering and seek an invitation to come over and try them out. Most hams love to show off their stations. Perhaps you have a nearby dealer who has some demo setups, or you can find some at a larger hamfest, or at Field Day. If you're in the northeast, drop by ARRL Headquarters and be a guest operator at W1AW — we have many radios available to try. Nothing beats a test drive!

# Extending HF Transceiver Coverage to Include VHF/UHF

Transceivers discussed so far include a wide range of features and operational capability. While some transceivers offer capability into the microwave region, most amateurs start with a transceiver that operates over the MF to HF frequency range, often extending into VHF at 6 meters. It is also true that most amateurs have at least a passing acquaintance with the higher VHF bands, perhaps 2 meter or 70 cm FM communications, through local repeaters.

At some point, many amateurs have heard enough about satellite communication or exotic beyond-line-of-sight propagation such as troposcatter, sporadic-E layer communication or moonbounce to want to try these activities. They take place using SSB, CW and narrow bandwidth digital modes, so a VHF/UHF FM transceiver won't do, although the FM satellites are almost as easy to use as the local repeater.

As noted previously, most HF transceivers cover 6 meters. Several also cover through the VHF bands, and some into UHF at 70 cm. These include the Elecraft KX3 with optional transverter, Icom IC-7100, Icom IC-705, Yaesu FT-818, and Yaesu FT-991A. Note that no current HF transceivers include transmission capability on the 1.25 meter band.

The Icom IC-9700 VHF/UHF multimode transceiver uses SDR technology to cover the 2 meter, 70 cm, and 23 cm bands. Power output is 100 W on 2 meters, 75 W on 70 cm, and 10 W on 23 cm. It incorporates many features that operators have come to expect in HF transceivers and performs well on all modes. Street price is about $1500.

**Icom IC-9700**

## Using an HF Transceiver at VHF/UHF

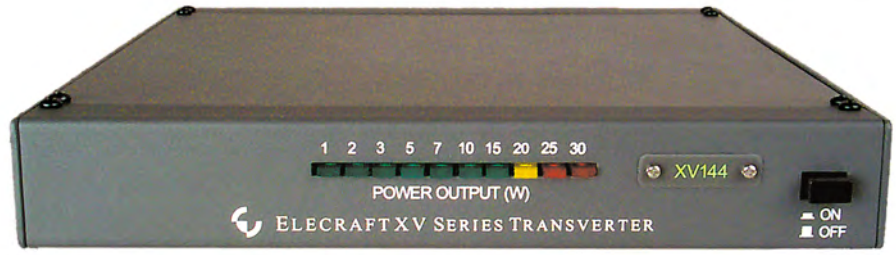
If you have the HF transceiver you want and would like to try the higher VHF and UHF bands, a viable option is a VHF or UHF transverter. A transverter essentially adds an additional conversion stage, along with pre- and post-amplification, to translate receive and transmit frequencies to a new range.

At VHF, UHF and microwave frequencies, transverters that interact with factory-made transceivers in the HF or VHF range are common and are often home-built. These units convert the transceiver transmit signal up to a higher frequency and convert the VHF/UHF receive frequency down to the transceiver receive frequency.

For microwave frequencies, it's common for transverters to have a 144-MHz IF for connection to a multimode 2 meter transceiver. Use of a higher IF frequency range makes image filtering easier. Sometimes transverters use two stages of conversion — microwave to 2 meters, and then 2 meters to 10 meters, for use with an HF transceiver.

The resulting performance and signal quality at the higher frequencies are enhanced by the frequency stability, bandwidth filters and signal processing capabilities of the transceiver. A transverter makes stable SSB and CW operation feasible on bands from 144 through 10 GHz and higher.

The interface between the transceiver and transverter requires some careful planning. For example, the transceiver power output must be compatible with the transverter's input requirements. This may require an



attenuator (or an amplifier) or some modifications to a particular transverter or transceiver. There is no standard level among transceiver and transverter brands, so check to see that your HF transceiver has a low-level transmitter output. Also important: a dedicated receiver input for transverter use, as well as some provision for TR switching.

The receive converter gain must not be so large that the transceiver front-end is overdriven, causing intermodulation and blocking. On the other hand, the transverter gain must be high enough and its noise figure low enough so that the overall system noise figure is within a dB or less of the transverter's own noise figure.

### TRANSVERTERS

If building a transverter from scratch is not for you, a number of manufacturers produce assembled or kit transverters for many VHF through microwave bands. Vendors include Down East Microwave (**www.downeastmicrowave.com**), Q5 Signal (**www.q5signal.com**), and Kuhne Electronics (DB6NT, **shop.kuhne-electronic.com/kuhne/en/**).

A number of online-only vendors are beginning to offer VHF, UHF, and microwave transverters for sale. Check e-commerce sites for availability. VHF+ clubs and user groups may have more information about quality and availability of these units which are often made by small companies in batches.

**Elecraft XV144**

**Down East Microwave L222-28**

## Transceivers for Use with Transverters

While almost any of the HF transceivers we have discussed can be made to operate with a transverter, some make for an easier fit than others. The key requirements for selecting a transceiver for transverter use are that they provide:

- Separate transmit and receive signal paths (not needed for all transverters).
- Control of RF output power down to low levels needed by most transverters. Having a separate low power transverter port avoids the chance that you will accidently put 100 W on 20 meters, for example, into your transverter.
- Transmit-receive switching control available to switch the transceiver and transverter in proper sequence. While on many radios the TR control output designed for linear amplifier switching can be pressed into service, a dedicated port for transverters is a plus.

In addition, nice but not absolutely necessary features are:

- A frequency display that indicates the transverter operating frequency directly rather than the transceiver's tunable IF frequency.
- The ability to input a frequency calibration offset to compensate for any error in the transverter's heterodyne oscillator frequency.

# Radio Mathematics

This supplement is a collection of tutorial information on a variety of mathematics used in Amateur Radio. Many of the fundamental relationships in electronics and radio are best expressed in the language of math. This chapter will expand in subsequent editions as it becomes clearer what information will be useful to readers. Material in this chapter has been collected from many sources, authors, and instructors over the years — the ARRL appreciates their contributions.

## 1 The Metric System

### 1.1 Metric Prefixes —the Language of Radio

The units of measurement employed in radio use the *metric system* of prefixes. The metric system is used because the numbers involved cover such a wide range of values. **Table 1** shows metric prefixes, symbols, and their meaning. The prefixes expand or shrink the units, multiplying them by the factor shown in the table. For example, a kilo-meter (km) is one thousand meters and a milli-meter (mm) is one-thousandth of a meter.

The most common prefixes you'll encounter in radio are pico (p), nano (n), micro (μ), milli (m), centi (c), kilo (k), mega (M) and giga (G). It is important to use the proper case for the prefix letter. For example, M means one million and m means one-thousandth. Using the wrong case would make a big difference!

The metric system uses a basic unit for each different type of measurement. For example, the basic unit of length is the *meter* (or metre). The basic unit of volume is the *liter* (or litre). The unit for mass (or quantity of matter) is the *gram*. The *newton* is the metric unit of force, or weight, but we often use the gram to indicate how "heavy" something is by assuming a standard value of gravity.

Table 1 summarizes the most-used *metric prefixes*. The metric system expresses larger or smaller quantities by multiplying or dividing the basic unit by factors of 10 (10, 100, 1000, 10,000 and so on). These multiples result in a standard set of prefixes, which can be used with all the basic units. Even if you come across some terms you are unfamiliar with, you will be able to recognize the prefixes.

We can write these prefixes as powers of 10, as shown in Table 1. The power of 10 (called the *exponent*) shows how many times you must multiply (or divide) the basic unit by 10. For example, we can see from the table that kilo means $10^3$. Let's use the meter as an example. If you multiply a meter by 10 three times, you will have a kilometer. (1 m $\times 10^3$ = 1 meter $\times 10 \times 10 \times 10$ = 1000 meters, or 1 kilometer.)

If you multiply 1 meter by 10 six times, you have a megameter. (1 meter $\times 10^6$ = 1 m $\times 10 \times 10 \times 10 \times 10 \times 10 \times 10$ = 1,000,000 meters or 1 megameter.)

Notice that the exponent for some of the prefixes is a negative number. This indicates that you must divide the basic unit by 10 that number of times. If you divide a meter by 10, you will have a decimeter. (1 meter $\times 10^{-1}$ = 1 m ÷ 10 = 0.1 meter, or 1 decimeter.) When we write $10^{-6}$, it means you must divide by 10 six

**Table 1**

**International System of Units (SI) — Metric Units**

| *Prefix* | *Symbol* | *Multiplication Factor* |
|---|---|---|
| Tera | T | $10^{12}$ = 1,000,000,000,000 |
| Giga | G | $10^{9}$ = 1,000,000,000 |
| Mega | M | $10^{6}$ = 1,000,000 |
| Kilo | k | $10^{3}$ = 1000 |
| Hecto | h | $10^{2}$ = 100 |
| Deca | da | $10^{1}$ = 10 |
| Deci | d | $10^{-1}$ = 0.1 |
| Centi | c | $10^{-2}$ = 0.01 |
| Milli | m | $10^{-3}$ = 0.001 |
| Micro | µ | $10^{-6}$ = 0.000001 |
| Nano | n | $10^{-9}$ = 0.000000001 |
| Pico | p | $10^{-12}$ = 0.000000000001 |

1 M = 1000 k; 1 m=1000 µ = 1,000,000 n; 1 µ=1000 n=1,000,000 p

times. (1 meter $\times 10^{-6}$ = 1 m ÷ 10 ÷ 10 ÷ 10 ÷ 10 ÷ 10 ÷ 10 = 0.000001 meter, or 1 micrometer.)

We can easily write very large or very small numbers with this system. We can use the metric prefixes with the basic units, or we can use powers of 10. Many of the quantities used in basic electronics are either very large or very small numbers, so we use these prefixes quite a bit. You should be sure you are familiar at least with the following prefixes and their associated powers of 10: giga ($10^{9}$), mega ($10^{6}$), kilo ($10^{3}$), centi ($10^{-2}$), milli ($10^{-3}$), micro ($10^{-6}$) and pico ($10^{-12}$).

Let's try an example. For this example, we'll use a term that you will run into quite often in the *Handbook*: hertz (abbreviated Hz, a unit that refers to the frequency of a radio wave). We have a receiver dial calibrated in kilohertz (kHz), and it shows a signal at a frequency of 28,450 kHz. Where would a dial calibrated in hertz show the signal? From Table 1 we see that kilo means times 1000. The basic unit of frequency is the hertz. That means that our signal is at 28,450 kHz ×1,000 = 28,450,000 hertz. There are 1000 hertz in 1 kilohertz, so 28,450,000 divided by 1000 gives us 28,450 kHz.

If we have a current of 3000 milliamperes, how many amperes is this? From Table 1 we see that milli means multiply by 0.001 or divide by 1000. Dividing 3000 milliamperes by 1000 gives us 3 amperes. The metric prefixes make it easy to use numbers that are a convenient size simply by changing the units. It is certainly easier to work with a measurement given as 3 amperes than as 3000 milliamperes!

Notice that it doesn't matter what the units are or what they represent. Meters, hertz, amperes, volts, farads or watts make no difference in how we use the prefixes. Each prefix represents a certain multiplication factor, and that value never changes.

## 1.2 Converting Between Types of Units

Converting between different types of units requires a *conversion factor*. The conversion factor is a value representing how many units of Type A are equivalent to a single unit of Type B, generally given as (amount of units of Type B) per (unit of Type A).

For example, the conversion factors between pounds (Type A) and kilograms (Type B) are 0.455 kg/lb and 2.2 lb/kg.

To decide which to use in converting units of Type A to Type B, select the factor with the Type B units in the numerator of the conversion factor. Multiply the amount of Type A units by the conversion factor.

For example, to convert 3 lb (Type A) to kg (Type B):

1. Select the conversion factor with Type B units (kg) in the numerator, 0.455 kg/lb

2. Multiply the amount of Type A units by the conversion factor: 3 lb × 0.455 lb/kg = 1.37 kg

Similarly, to convert 3 kg (Type A) to lb (Type B):

1. Select the conversion factor with Type B units (lb) in the numerator, 2.2 lb/kg

2. Multiply 3 kg × 2.2 lb/kg = 6.6 lb

Note that these conversion factors are reciprocals. You can change one conversion factor into the other by calculating 1 divided by the conversion factor. Exchange the numerator and denominator at the same time:

1/ (0.455 kg/lb) = 2.2 lb/kg and 1/ (2.2 lb/kg) = 0.455 kg/lb

You can also convert Type B units into Type A by dividing the amount of Type B units by the conversion factor from Type A to Type B:

10 kg / 0.455 kg/lb = 22 lb

Note that not all conversions are simple multiplications or divisions. Additional offsets or factors may be required. For example, to convert degrees Fahrenheit to degrees Celsius, the formula is:

Deg C = 5/9 × (Deg F – 32)

The *Handbook's* **Component Data and References** chapter includes a table of conversion factors for US Customary Units and between US Customary Units and Metric Units. Online calculators abound. Google (**www.google.com**) provides a unit converter accessible by entering "convert [abbreviation or name for Type A units] to [abbreviation or name for Type B units]" into an Internet search window.

# 2 Numbers and Notation

## 2.1 Accuracy, Resolution, and Precision

The terms accuracy, precision, and resolution are often confused and used interchangeably, when they have very different meanings. When dealing with measurements and test instruments, it's important to keep them straight.

• *Accuracy* is the ability of an instrument to make a measurement that reflects the actual value of the parameter being measured. An instrument's accuracy is usually specified in percent or decibels (see below) referenced to some known standard.

• *Precision* refers to the smallest division of measurement that an instrument can make repeatedly. For example, a metric ruler divided into mm is more precise than one divided into cm.

• *Resolution* is the ability of an instrument to distinguish between two different quantities. If the smallest difference a meter can distinguish between two currents is 0.1 mA, that is the meter's resolution.

It is important to note that the three qualities are not necessarily mutually guaranteed. That is, a precise meter may not be accurate, or the resolution of an accurate meter may not be very high, or the precision of a meter may be greater than its resolution. It is important to understand the difference between the three.

## 2.2 Accuracy and Significant Figures

The calculations you will find throughout the *Handbook* follow the rules for accuracy of calculations. Accuracy is represented by the number of *significant digits* in a number. That is, the number of digits that carry numeric value information beyond order of magnitude. For example, the numbers 0.123, 1.23, 12.3, 123, and 1,230 all have three significant digits.

The result of a calculation can only be as accurate as its *least* accurate measurement or known value. This is important because it is rare for measurements to be more accurate than a few percent. This limits the number of useful significant digits to two or three. Here's another example; what is the current through a 12-Ω resistor if 4.6 V is applied? Ohm's Law says I in amperes = 4.6 / 12 = 0.3833333... but because our most accurate numeric information only has two significant digits (12 and 4.6), strictly applying the significant digits calculation rule limits our answer to 0.38. One extra digit is often included, 0.383 in this case, to act as a guide in rounding off the answer.

Quite often this occurs because a calculator is used, and the result of a calculation fills the numeric window. Just because the calculator shows 9 digits after the decimal point does not mean that is a more correct or even useful answer.

## 2.3 Scientific and Engineering Notation

Modern electronics often uses numbers that are either quite large or very close to zero. At either extreme, it is difficult to write the numbers because of all the zeros. For example, the speed of light at which radio waves travel in a vacuum is 300,000,000 m/s. Similarly, a 22 pF capacitor would be written as 0.000000000022 F. These are values written in *decimal form* where all of the significant digits are present, including the place-holding zeros. This is a very inconvenient format for calculation.

Instead, most large and small values in electronics are written in a special type of *exponential notation* called *scientific notation*. Numbers written this way consist of a value multiplied by 10 raised to an integer power. A number written in normalized scientific notation looks like this:

$$\pm D.DD \times 10^{\pm EE}$$

where D.DD is a decimal value between 1 and 10, such as 3.14 or 7.07. EE is an exponent of 10, generally between 0 and 99. The following are a few ways of writing the same number in scientific notation several ways:

$567\ \text{kHz} = 5.67 \times 10^{5}\ \text{Hz}$
$= 5.67 \times 10^{2}\ \text{kHz}$
$= 5.67 \times 10^{-1}\ \text{MHz}$
$= 5.67 \times 10^{-4}\ \text{GHz}$

Because electronic units of measurements generally follow metric prefixes such as μF or MHz, it is most convenient to give values in these units while still using the general form of scientific notation. This is called *engineering notation*. For engineering notation, the exponent must be a multiple of 3, such as –6, –3, 3, 6, or 12. These correspond to the various metric prefixes listed earlier. This means the number is written:

$$\pm DDD.DD \times 10^{\pm EE}\ \text{(units)}$$

Because standard units are used, engineering notation is easier to work with. For example, the most convenient units can be used throughout a calculation:

$2.47\ \text{V} = 2.47 \times 10^{0}\ \text{V}$
$= 2.47 \times 10^{3}\ \text{mV}$
$= 2.47 \times 10^{6}\ \mu\text{V}$

Similarly, the value of a 151 kΩ resistor could be written several ways:

$151\ \text{k}\Omega = 151 \times 10^{3}\ \Omega$
$= 151 \times 10^{0}\ \text{k}\Omega$
$= 151 \times 10^{-3}\ \text{M}\Omega$

Your calculator may have the ability to perform calculations in exponential, scientific, and engineering notation. It is worth figuring out how to use these formats if you plan on doing any electronic value calculations.

## 2.4 Rate of Change

The symbol Δ represents "change in" a following variable, so that ΔI represents "change in current" and Δt "change in time". A rate of change per unit of time is often expressed in this manner. When the amount of time over which the change is measured becomes very small, the letter *d* replaces Δ in both the numerator and denominator to indicate infinitesimal changes. This notation is often used in functions that describe the behavior of electric circuits.

# 3 Decibels

*Decibels* (abbreviated *dB*) are just a way of expressing ratios, usually power ratios. If you are looking at the gain of an amplifier stage, the pattern of an antenna, or the loss of a transmission line you are generally interested in the ratio of output power to input power. In antenna work, you are often concerned with the ratio of the power coming from the front of a beam antenna to that coming from the back. These are some of the places where you will find the results expressed in dB.

Decibels are a logarithmic function. An important feature of logarithms is that you can perform multiplication by adding logarithmic quantities instead of multiplying them. Similarly, you can divide numbers by subtracting in the same manner. This becomes a benefit if you are dealing with multiple stages of amplification and attenuation — as you often are doing in radio systems. In a radio receiver instead of having to multiply and divide the gains or losses of each stage to keep track of the signal processing — often with signal levels with many zeros to the right of the decimal point — you can just add up all the dB and determine the total gain in the system.

The *deci* in decibels refers to a factor of 1/10, as in *deciliters* for ⅒ of a liter, while the *bel* relates to the idea of a logarithmic ratio, originally used to define sound power. The bel was named after Alexander Graham Bell, the inventor of the telephone.

## 3.1 Calculating Decibels from Ratios

To convert a power ratio into decibels:
1. Find the base 10 logarithm of the power ratio.
2. Multiply by 10.

$$dB = 10 \log_{10} (\text{power ratio})$$

The same decibels can be used to represent voltage or current ratios, rather than power ratios. Since power goes up with the square of the voltage or current, assuming the same impedance, the voltage or current ratios must be squared as well. With logarithms, ratios are squared merely by multiplying by two. Thus everything works the same way as for power calculations, except we multiply (or divide) by 20 instead of 10:

$$dB = 20 \log_{10} (\text{voltage or current ratio})$$

If you are comparing a measured power or voltage ($P_M$ or $V_M$) to some reference power ($P_{REF}$ or $V_{REF}$) the formulas are:

$$dB = 10 \log_{10} \left( \frac{P_M}{P_{REF}} \right) = 20 \log_{10} \left( \frac{V_M}{V_{REF}} \right)$$

Positive values of dB mean the ratio is greater than 1 and negative values of dB indicate a ratio of less than 1. Ratios greater than 1 can be referred to as *gain*, while ratios less than 1 can be called a *loss* or *attenuation*. Note that loss and attenuation are often given as positive values of dB (for example, "a loss of 10 dB" or "a 6 dB attenuator") with the understanding that the ratio is less than one and the calculated value of change in dB will be negative.

For example, if an amplifier turns a 5-watt signal into a 25-watt signal, that's a gain of:

$$dB = 10 \log_{10} \left( \frac{25}{5} \right) = 10 \log_{10} (5) = 10 \times (0.7) = 7 \text{ dB}$$

On the other hand, if by adjusting a receiver's volume control the audio output signal voltage is reduced from 2 volts to 0.1 volt, that's a change of:

$$dB = 20 \log_{10} \left( \frac{0.1}{2} \right) = 20 \log_{10} (0.05) = 20 \times (-1.3) = -26 \text{ dB}$$

A very useful value to remember is that any time you double the power (or cut it in half), there is a 3 dB change. A two-times increase (or decrease) in power results in a gain (or loss) of:

$$dB = 10 \log_{10} \left( \frac{2}{1} \right) = 10 \log_{10} (2) = 10 \times (0.3) = 3 \text{ dB}$$

See the sidebar "Decibels In Your Head" for a guide to easy values of dB you can remember and apply quickly without having to use a calculator.

### Decibels In Your Head

Increasing power by a factor of 2 is a 3-dB increase and a factor of 4 increase is a 6-dB increase. When you increase power by 10 times, you have an increase of 10 dB. You can also use these same values for decreasing power. Cut power in half for a 3-dB loss of power. Reduce power to ¼ the original amount for a 6-dB loss. Reducing power to ⅒ of the original amount is a 10-dB loss. Power-loss values are written as negative values: –3, –6 or –10 dB. The following tables show these common decibel values and ratios.

You can also derive all the dB equivalents of integer ratios by adding or subtracting dB values. For example, to calculate a power ratio of 10/4 (2.5) in dB, subtract the dB equivalents for 10 and 4: 10 – 6 = 4 dB. Similarly for a ratio of 10/2 (5), 10 – 3 = 7 dB. The ratio of 5/4 (1.25) is 7 – 6 = 1 dB and so forth. The same trick can be used with the voltage ratios.

## 3.2 Calculating Ratios and Percentages from Decibels

To convert decibels to a power ratio, we do the opposite:
1. Divide by 10 (or 20 if converting to a voltage or current ratio)
2. Find the base 10 antilog of the result.

Note that the base 10 antilog of a number is just 10 raised to the power of the number. This is also something you probably don't do in your head, so let's see how you can easily perform the computations.

Understanding a few characteristics of logs will help avoid problems interpreting results. Note that a gain of 0 dB, means that there is no change to the signal — not that the signal has vanished! The other important fact is that a power ratio of less than one (a loss rather than a gain) results in a negative number in decibels.

$$\text{power ratio} = \log^{-1} \left( \frac{dB}{10} \right) \text{ and}$$

$$\text{voltage ratio} = \log^{-1} \left( \frac{dB}{20} \right)$$

Note that the antilog is the same as the inverse log (written as $\log_{10}{}^{-1}$ or just $\log^{-1}$). Most calculators use the inverse log notation. On scientific calculators the inverse log key may be labeled $LOG^{-1}$, ALOG, or $10^X$, which means "raise 10 to the power of this value." Some calculators require a two-button sequence such as INV then LOG.

**Example 1:** A power ratio of 9 dB = $\log^{-1}$ (9 / 10) = $\log^{-1}$ (0.9) = 8
**Example 2:** A voltage ratio of 32 dB = $\log^{-1}$ (32 / 20) = $\log^{-1}$ (1.6) = 40

Since percentage is already a ratio, you can work directly in percentages when converting to dB:

$$dB = 10 \log\left(\frac{\text{Percentage Power}}{100\%}\right)$$

$$dB = 20 \log\left(\frac{\text{Percentage Voltage}}{100\%}\right)$$

To convert back to percentages, just multiply the calculated ratio by 100%:

$$\text{Percentage Power} = 100\% \times \log^{-1}\left(\frac{dB}{10}\right)$$

$$\text{Percentage Voltage} = 100\% \times \log^{-1}\left(\frac{dB}{20}\right)$$

Here's a practical application for converting dB to percentages and vice versa. Suppose you are using an antenna feed line with a signal loss of 1 dB. You can calculate the amount of transmitter power that's actually reaching your antenna and how much is lost in the feed line.

$$\text{Percentage Power} = 100\% \times \log^{-1}\left(\frac{-1}{10}\right) = 100\% \times \log^{-1}(-0.1) = 79.4\%$$

So 79.4% of your power is reaching the antenna and 20.6% is lost in the feed line.

**Example 3:** A power ratio of 20% = 10 log (20% / 100%) = 10 log (0.2) = –7 dB

**Example 4:** A voltage ratio of 150% = 20 log (150% / 100%) = 20 log (1.5) = 3.52 dB

**Example 5:** –3 dB represents a percentage power = 100% × $\log^{-1}$ (–3 / 10) = 50%

**Example 6:** 4 dB represents a percentage voltage = 100% × $\log_{-1}$ (4 / 20) = 158%

## 3.3 Using the *Windows* Scientific Calculator

If you have a suitable scientific calculator, it should easily do your calculations. Not all have an ANTILOG button, but if not, they will likely have a button that says X^Y, which can be used as above. If you don't have a handheld calculator, you can use the Calculator accessory in the Microsoft *Windows* operating system For *Windows 7* and earlier versions, click START, then ALL PROGRAMS, then ACCESSORIES. For *Windows 10*, click START, then look in the menu for CALCULATOR.

**Figure 1 — Screen shot of the *Windows 10* scientific calculator ready to find the power loss of 2 dB.**

On first opening the calculator, you may find a four-function Standard calculator. To change to a Scientific calculator in the *Windows 7* and earlier versions, click on VIEW**,** then SCIENTIFIC to get the one you want. In the *Windows 10* version, click the MENU icon and select SCIENTIFIC. The *Windows 10* version is shown in **Figure 1**.

Let's say you have a mismatched coax cable with a loss of 2 dB. You may want to know how much of the 100 W generated by your transmitter actually reaches your antenna. Remember, a 2 dB loss is a "gain" of –2 dB. Using your *Windows Calculator*:

- Press 2 on your keyboard, or click 2 on the calculator keypad.
- Click on the ± key, then ÷, 1, 0, and =. The display should show –0.2, as in Figure 1.
- Click on $10^X$ to raise 10 to the power of –0.2.

The display should show 0.6309573444 (a number with many digits), which is about 0.63. That is the fraction of power left after a 2 dB loss. That means of the 100 W transmitted, the antenna sees 63 W and 37 W is heating the feed line.

**Table 2**

**Common dB Values For Ratios of Power and Voltage**

| *P2/P1* | *dB* | *V2/V1* | *dB* |
|---|---|---|---|
| 0.1 | –10 | 0.1 | –20 |
| 0.25 | –6 | 0.25 | –12 |
| 0.5 | –3 | 0.5 | –6 |
| 1 | 0 | 0.707 | –3 |
| 2 | 3 | 1 | 0 |
| 4 | 6 | 1.414 | 3 |
| 10 | 10 | 2 | 6 |
| | | 4 | 12 |
| | | 10 | 20 |

## 3.4 Decibel Calculation with Special References

While the general use of decibels is as a ratio of input to output, they are also used to represent particular power or voltage levels by defining the base power or voltage at a particular level. In this case, the dB units will have a suffix indicating the reference. For example, to indicate power compared to 1 W, we would use the symbol dBW. For example, a signal level of 13 dBW would indicate power of 13 dB greater than 1 W which is 200 W. Other common references are shown below:

dBd — decibels of gain with respect to a dipole antenna in its preferred direction

dBi — decibels of gain with respect to that of an ideal isotropic antenna

dBmV — voltage level in decibels compared to a millivolt

dBµV — voltage level in decibels compared to a microvolt

dBm (dBmW) — power level in decibels compared to a milliwatt

dBµW — power level in decibels compared to a microwatt

For example, if we had an amplifier with a gain of 30 dB and applied an input signal of 10 dBm, we would have an output power of 40 dBm or 10 dBW, which is 10 W. Note that the amplifier gain is in dB, a unitless ratio, while the input and output levels are in dBm or dBW, representing particular powers.

# 4 Coordinate Systems

## 4.1 Rectangular and Polar Coordinates

Graphs are drawings of what equations describe with symbols — they're both saying the same thing. The way in which mathematical quantities are positioned on the graph is called the *coordinate system*. *Coordinate* is another name for the numeric scale that divides the graph into regular units. The location of every point on the graph is described by a set of *coordinates*.

The two most common coordinate systems used in radio are the *rectangular-coordinate* system shown in **Figure 2A** (sometimes called *Cartesian coordinates*) and the *polar-coordinate* system shown in Figure 2B.

The line that runs horizontally through the center of a rectangular coordinate graph is called the *X axis*. The line that runs vertically through the center of the graph is called the *Y axis*. Every point on a rectangular coordinate graph has two coordinates that identify its location, X and Y, also written as (X,Y). Every different pair of coordinate values describes a different point on the graph. The point at which the two axes cross — where the numeric values on both axes are zero — is called the *origin*, written as (0,0).

In Figure 2A, the point with coordinates of (3,5) is located 3 units to the right of the origin along the X axis and 5 units above the origin along the Y axis. Another point at (–2,–4) is found 2 units to the left of the origin along the X axis and 4 units below the origin along the Y axis.

In the polar-coordinate system, points on the graph are also described by a pair of numeric values called *polar coordinates*. In this case we use a length, or *radius*, measured from the origin, and an *angle* from 0° to 360° measured counterclockwise from the 0° line as shown in Figure 2B. The symbol *r* is used for the radius and θ for the angle. A number in polar coordinates is written r∠θ. So the two points described in the last paragraph could also be written as (5.83, ∠59.0°) and (4.5, ∠243.4°) and are drawn as polar coordinates in Figure 2B. Remember that unlike maps, the 0º direction is always to the *right* and not to the top. In mathematics, 0° is not north!

A negative angle essentially means, "turn the other way." With positive angles measured counterclockwise from the 0° axis, the polar coordinates of the point at lower left in Figure 2B would be (4.5, ∠–116.6°). When you encounter a negative value for the angle, it means to measure the angle clockwise from 0°. For example, –270° is equivalent to 90°; –90° is equivalent to 270°; 0° and –360° are equivalent; and +180° and –180° are equivalent. An angle can also be specified in *radians* (1 radian = 360 / 2π = 57.3 degrees) but all angles are in degrees in the *Handbook* unless stated otherwise.

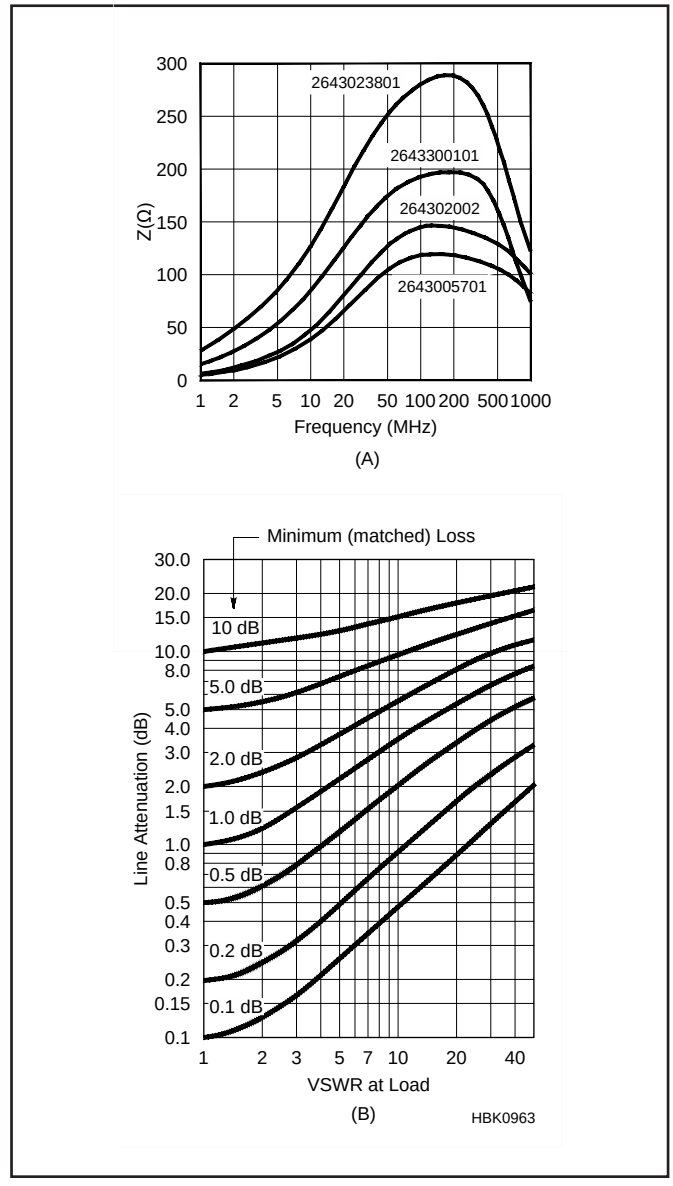

**Figure 3 — A semi-log graph (A) with a logarithmic horizontal axis and linear vertical axis. A log-log graph (B) with both horizontal and vertical axes have a logarithmic scale.**

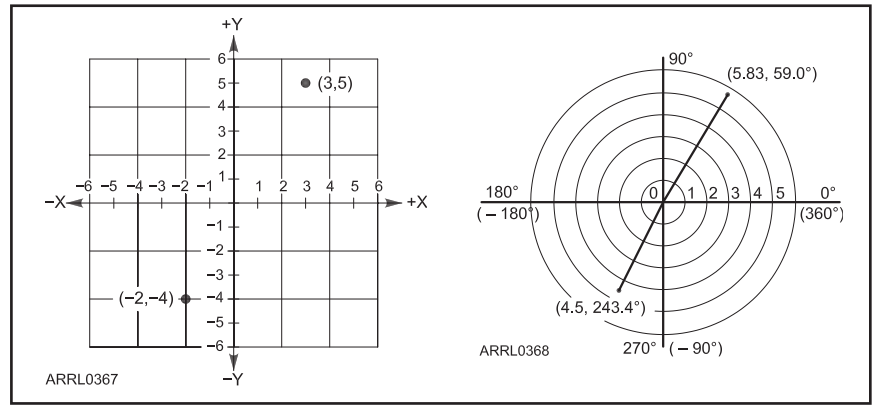

**Figure 2 — Rectangular-coordinate graphs (A) use a pair of axes at right angles to each other, each calibrated in numeric units. Any point on the resulting grid and be expressed in terms of its horizontal (X) and vertical (Y) values, called coordinates. Polar-coordinate graphs (B) use a radius from the origin and an angle from the 0° axis to specify the location of a point. Thus, the location of any point can be specified in terms of a radius (r) and an angle (θ).**

## SEMI-LOG AND LOG-LOG GRAPHS

Many elements of radio and electronics have at least one aspect that behaves logarithmically or exponentially. Graphing that behavior is difficult or unclear if a linear scale is used since the ranges of the variables are usually quite large. A linear scale tends to compress all the "interesting" behavior into a corner or along one edge of the chart. In order to better view the behavior, the semi-log and log-log charts were created. (See **Figure 3**.)

The semi-log chart has one axis in which the scale is divided logarithmically. Figure 3A shows the relationship between impedance of ferrite beads on the vertical (Y) axis and frequency on the horizontal (X) axis. This allows the impedance to be plotted over the entire frequency range of 1 MHz to 1 GHz. If a linear scale was used for frequency, the curve would be quite flat and it would be difficult to see the peak. When one variable has a limited range (impedance in this case) and the other has a wide range, a semi-log graph is often best.

The log-log chart in Figure 3B shows the relationship between two logarithmic variables — line loss and frequency. Both variables have a very wide range. The use of the log scale for line loss in dB greatly

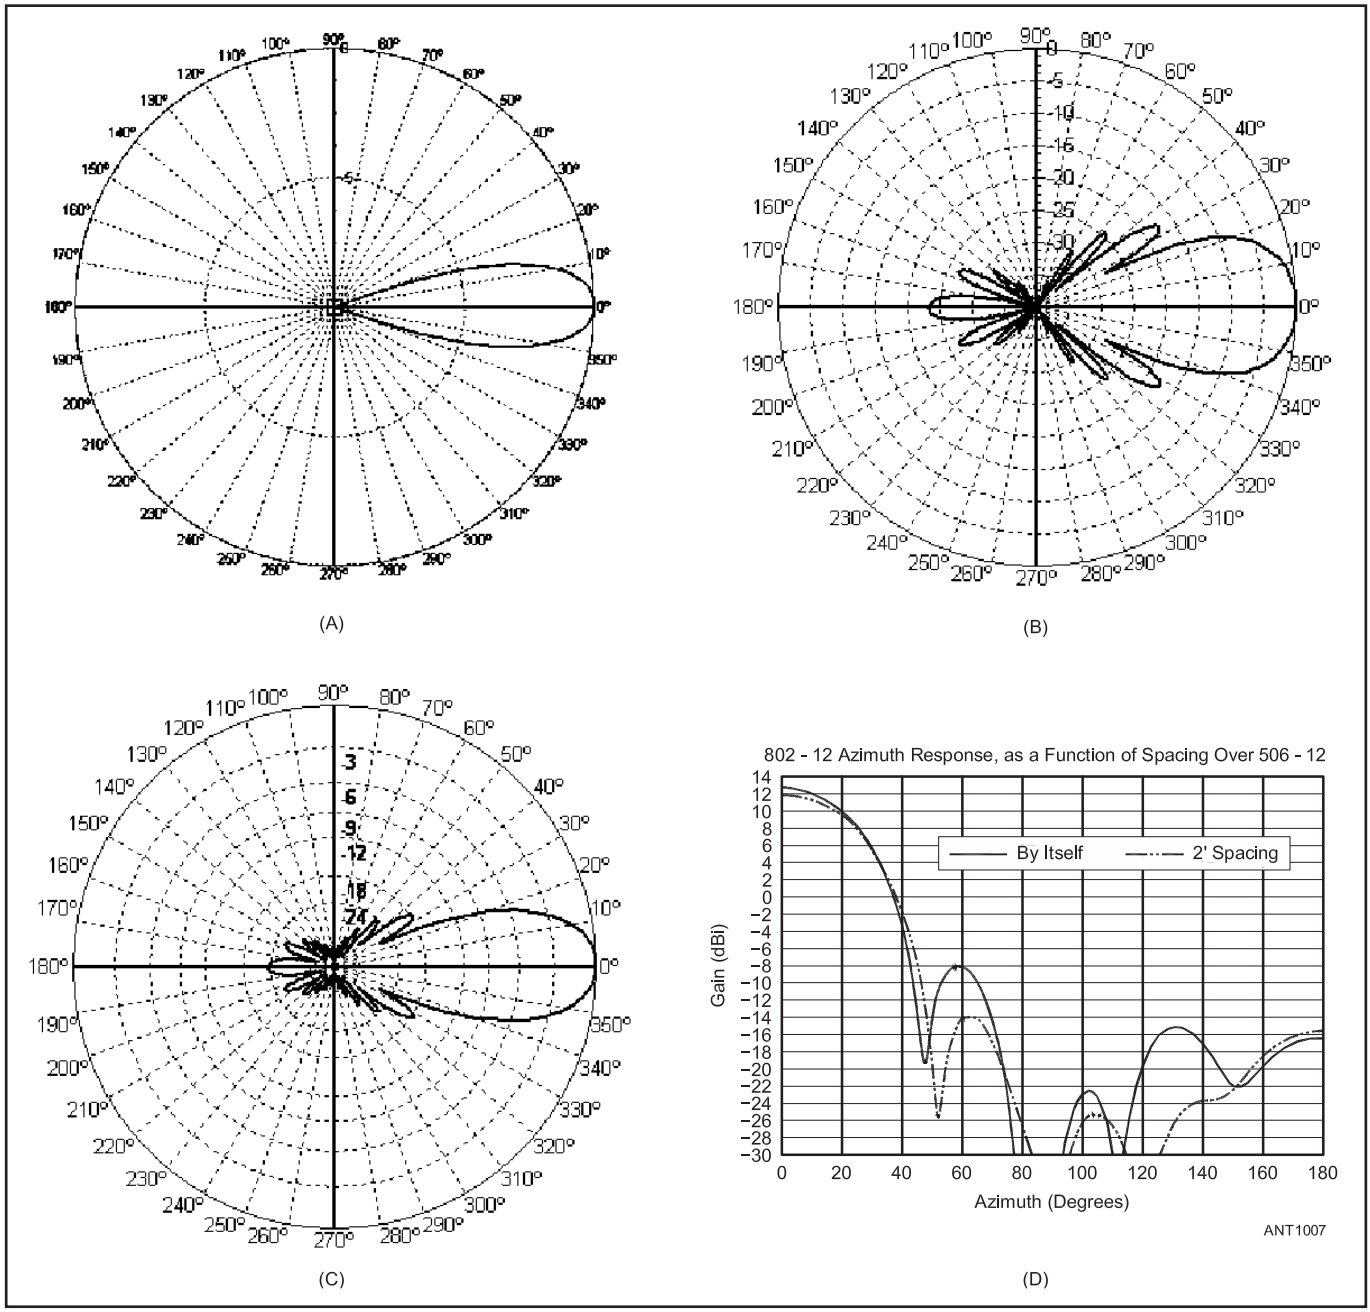

**Figure 4 — Radiation pattern plots for a high-gain Yagi antenna on different grid coordinate systems. At A, the pattern on a linear-power dB grid. Notice how details of side lobe structure are lost with this grid. At B, the same pattern on a grid with constant 5 dB circles. The side lobe level is exaggerated when this scale is employed. At C, the same pattern on the modified log grid used by ARRL. The side and rearward lobes are clearly visible on this grid. The concentric circles in all three grids are graduated in decibels referenced to 0 dB at the outer edge of the chart. The patterns look quite different, yet they all represent the same antenna response! D shows the rectangular azimuthal patterns of two VHF Yagi antennas. This example shows how a rectangular plot allows easier comparison of antenna patterns away from the main lobe.**

expands the area occupied by the line loss curves at low VSWR, which is of most interest. If the vertical scale was not logarithmic, the family of curves would be very compressed in the region of primary interest and difficult to read. When both variables have a very wide range, use a log-log graph.

## 4.2 Coordinates for Radiation Patterns

A number of different systems of coordinate scales or grids are in use for plotting antenna patterns. (Antenna radiation patterns are discussed in the **Antennas** chapter.) Antenna patterns published for amateur audiences are sometimes placed on rectangular grids, but more often they are shown using polar coordinate systems. Polar coordinate systems may be divided generally into three classes: *linear*, *logarithmic* and *modified logarithmic*.

A very important point to remember is that the shape of a pattern (its general appearance) is highly dependent on the grid system used for the plotting. This is exemplified in **Figure 4**, where the radiation pattern for a beam antenna is presented using three coordinate systems described below.

### LINEAR COORDINATE SYSTEMS

The polar coordinate system in Figure 4A uses linear coordinates. The concentric circles are equally spaced, and are graduated from 0 to 10. Such a grid may be used to prepare a linear plot of the power contained in the signal. For ease of comparison, the equally spaced concentric circles have been replaced with appropriately placed circles representing the decibel response, referenced to 0 dB at the outer edge of the plot. In these plots the minor lobes are suppressed. Lobes with peaks more than 15 dB or so below the main lobe disappear completely because of their small size. This is a good way to show the pattern of an array having high directivity and small minor lobes. Linear coordinate patterns are not common, however.

### LOGARITHMIC COORDINATE SYSTEM

Another coordinate system used by antenna manufacturers is the logarithmic grid, where the concentric grid lines are spaced according to the logarithm of the voltage of the signal. If the logarithmically spaced concentric circles are replaced with appropriately placed circles representing the decibel response, the decibel circles are graduated linearly. In that sense, the logarithmic grid might be termed a linear-log grid, one having linear divisions calibrated in decibels.

This grid enhances the appearance of the minor lobes. If the intent is to show the radiation pattern of an array supposedly having an omnidirectional response, this grid enhances that appearance. An antenna having a difference of 8 or 10 dB in pattern response around the compass appears to be closer to omnidirectional on this grid than on any of the others. See Figure 4B.

### ARRL LOG COORDINATE SYSTEM

The modified logarithmic grid used by the ARRL has a system of concentric grid lines spaced according to the logarithm of 0.89 times the value of the signal voltage. In this grid, minor lobes that are 30 and 40 dB down from the main lobe are distinguishable. Such lobes are of concern in VHF and UHF operation. The spacing between plotted points at 0 dB and –3 dB is significantly greater than the spacing between –20 and –23 dB, which in turn is significantly greater than the spacing between –50 and –53 dB.

For example, the scale distance covered by 0 to 3 dB is about 1/10 of the radius of the chart. The scale distance for the next 3-dB increment (to –6 dB) is slightly less, 89% of the first, to be exact. The scale distance for the next 3-dB increment (to –9 dB) is again 89%

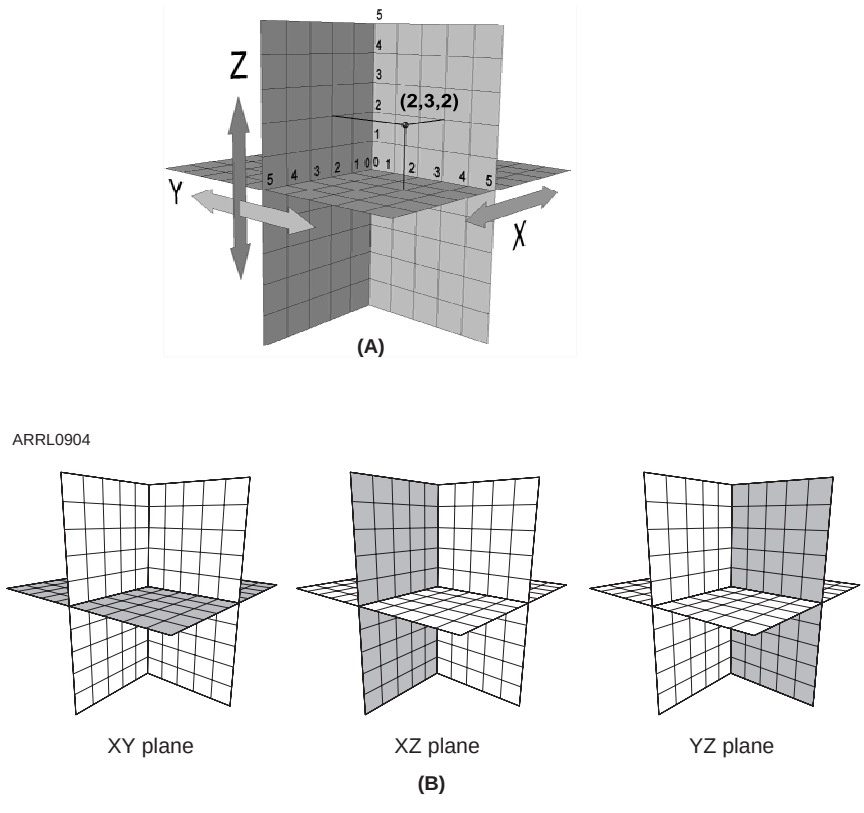

**Figure 5 — In a three-dimensional rectangular coordinate system (A), a third axis, the Z axis, is added at right angles to both the X and Y axes. In X-Y-Z coordinates, the three coordinates can be used to specify a point's location anywhere in space. The set of axes has been oriented to show all three positive axes. Three rectangular coordinate planes (B). Each pair of axes creates a plane in which the coordinate for the third axis is zero. All points in the X-Y plane have a Z coordinate of zero, for example. The set of axes has been oriented to show all three positive axes.**

of the second. The scale is thus constructed so that the inner-most two circles represent –36 and –48 dB and the chart center represents –100 dB.

The periodicity of spacing thus corresponds generally to the relative significance of such changes in antenna performance. Antenna pattern plots in ARRL publications are usually made on the modified-log grid similar to that shown in Figure 4C.

### RECTANGULAR GRID

Antenna radiation patterns can also be plotted on rectangular coordinates with gain on the vertical axis in dB and angle on the horizontal axis as shown in Figure 4D. Multiple patterns in polar coordinates can be difficult to read, particularly close to the center of the plot. Using a rectangular grid makes it easier to evaluate low-level minor lobes and is especially useful when several antennas are being compared.

## 4.3 Three-Dimensional Coordinate Systems

### RECTANGULAR (X-Y-Z)

**Figure 5A** adds a third axis, the *Z axis*, to the X and Y axes. This creates a three-dimensional system of coordinates in which any location is specified by three numbers instead of two. In Figure 5A, the indicated point's location is 2 units along the X axis, 3 units along the Y axis, and 2 units along the Z axis. The X and Y axis are usually assigned to be the "horizontal" plane and the Z axis to be "height" above the horizontal plane.

Each pair of axes defines a *plane* — an infinitely thin sheet that extends to infinity along both axes. The X-Y-Z coordinate system has three such planes as illustrated in Figure 5B. For all points in each of these planes, one coordinate is always zero: in the X-Y plane, the Z coordinate is zero, in the Y-Z plane, the X coordinate is zero, and in the X-Z plane, the Y coordinate is zero.

### CYLINDRICAL (R, θ, Z)

As when specifying the location of points in the X-Y plane using polar coordinates, *r* is used for the radius. The Greek letter theta (θ) is used for the angle which is measured counterclockwise from the 0° line as shown. A number in polar coordinates is written r∠θ.

If the Z axis is added, a cylinder is created with a radius of *r* and a height of *z*. The angle θ defines a vertical line along the cylinder. The type of coordinate system in **Figure 6** is called *cylindrical coordinates* and a point's location is given as (*r*, θ, *z*).

### SPHERICAL (R, θ, ϕ) OR AZIMUTH-ELEVATION

Instead of using Z as a third coordinate, another useful method of locating a point is with a second angle as shown in **Figure 7**, creating *spherical coordinates*. The angle in the X-Y plane (θ) is called the *azimuth* angle and it corresponds to direction in the horizontal plane. The second angle, ϕ, is measured between the horizontal plane and the point and is called the *elevation* angle.

When used in the real world, elevation is measured from the horizontal plane to the point, so a point on the ground has an elevation of 0° and a point directly overhead at the *zenith* has an elevation of 90°.

In spherical coordinates, the position of a point is given as (r, θ, ϕ). Spherical coordinates are the standard used by antenna modelers to describe antenna radiation patterns and the coordinates (r, azimuth, and elevation) are used.

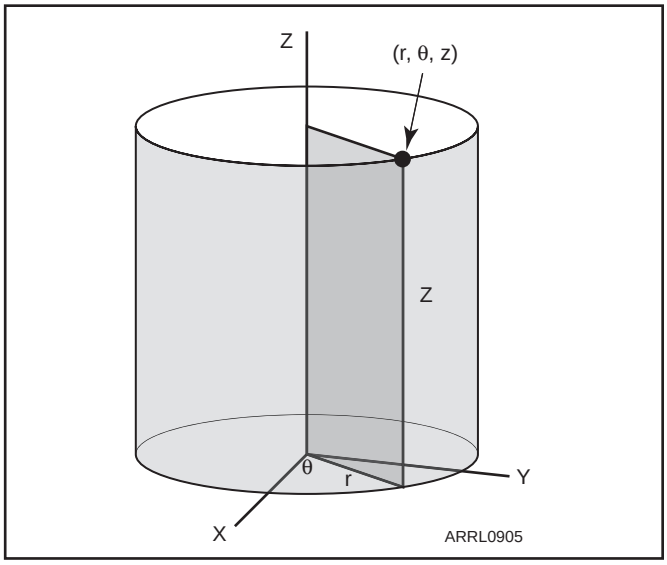

**Figure 6 — Cylindrical coordinates. By adding a Z coordinate, a cylinder is created whose center is at the origin with a radius of r and a height of z. A point's location in cylindrical coordinates is specified as (r, θ, z).**

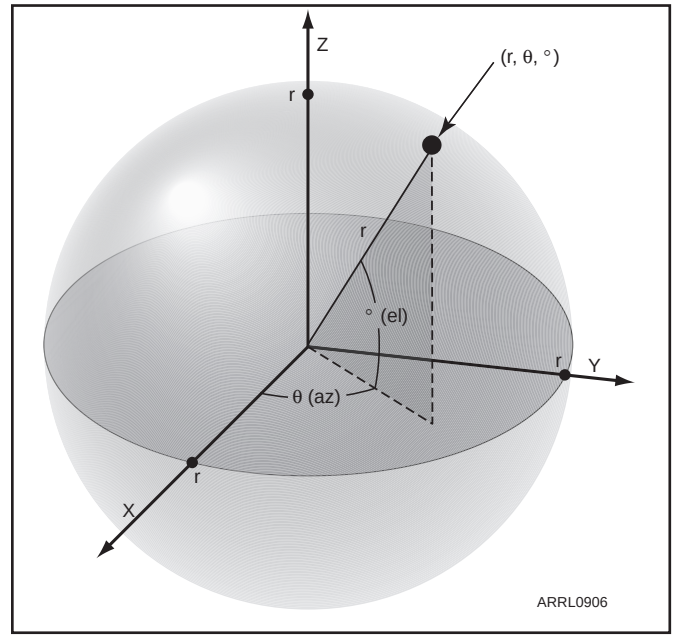

**Figure 7 — Spherical coordinates. Each point lies on the surface of a sphere with its center at the origin. The position of the point is given as the radius of the sphere, r, and the azimuth (θ) and elevation (ϕ) angles.**

# 5 Exponential Equations

An exponential equation is one in which the variable is an exponent of a constant, another variable, or some kind of mathematical formula (expression). By far, the most common exponential equations in electronics and radio are based on the number *e*, or *Euler's number*, which has a value of 2.71828… Similarly to the transcendental number $\pi$ (3.14159…), the value of *e* is irrational and has an infinite number of digits. It is the base of the *natural logarithm*, which in written $\log_e$ or ln.

The most common use of *e* in electronics is in calculating the charging and discharging time constants of capacitor and inductor circuits. Two typical equations that form the basis of timing calculations are:

Charging: $V(t) = E\,(1 - e^{-t/\tau})$

Discharging: $V(t) = E\,(e^{-t/\tau})$

where V(t) is the voltage across a capacitor changing with time, E represents the final dc voltage (charging) or the initial dc voltage (discharging) across the capacitor, $\tau$ (tau) is the circuit's *time constant* which is determined by the circuit component values, and *t* is time. (These circuits are discussed in more detail in the chapter on **Electrical Fundamentals**. Similar equations apply to current in an inductor.)

The capacitor charging and discharging voltages are show in **Figure 8**, where the time axis is shown in terms of $\tau$ and the vertical axis is expressed as a percentage of the applied voltage. These graphs are representative of all simple RC and RL circuits.

These equations can be solved fairly easily with a calculator that is able to work with natural logarithms (it will have a key labeled LN or LN X). You can also calculate the value for $e^{-t/\tau}$ as the inverse natural log of $-t / \tau$, written as $\ln^{-1}(-t / \tau)$.

As shown on the graphs of Figure 8, it is common practice to think of charge or discharge time in terms of multiples of the circuit's time constant. If we select times of zero (starting time), one time constant ($1\tau$), two time constants ($2\tau$), and so on, then the exponential term in the equations simplifies to $e^0$, $e^{-1}$, $e^{-2}$, $e^{-3}$ and so forth. Then we can solve the equations for those values of time.

Using the example of a capacitor being charged, assume that a dc voltage E = 100 V is applied so that the voltages will have the same value as a percentage of E.

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| $V(0) = 100\text{ V}\,(1 - e^{0})$ | = | $100\text{ V}\,(1 - 1)$ | = | 0 V, | or | 0% |
| $V(1\tau) = 100\text{ V}\,(1 - e^{-1})$ | = | $100\text{ V}\,(1 - 0.368)$ | = | 63.2 V, | or | 63.2% |
| $V(2\tau) = 100\text{ V}\,(1 - e^{-2})$ | = | $100\text{ V}\,(1 - 0.135)$ | = | 86.5 V, | or | 86.5% |
| $V(3\tau) = 100\text{ V}\,(1 - e^{-3})$ | = | $100\text{ V}\,(1 - 0.050)$ | = | 95.0 V, | or | 95% |
| $V(4\tau) = 100\text{ V}\,(1 - e^{-4})$ | = | $100\text{ V}\,(1 - 0.018)$ | = | 98.2 V, | or | 98.2% |
| $V(5\tau) = 100\text{ V}\,(1 - e^{-5})$ | = | $100\text{ V}\,(1 - 0.007)$ | = | 99.3 V, | or | 99.3% |

After a time equal to five time constants has passed, the capacitor is charged to 99.3% of the applied voltage. This is fully charged for all practical purposes.

The equation used to calculate the capacitor voltage while it is discharging is slightly different from the one for charging. The resulting curve, though, is similar to the charging curve. For values of time equal to multiples of the circuit time constant:

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| $t = 0,$ | $e^{0}$ | = | 1, | so V(0) | = | 100 V, | or | 100% |
| $t = 1\tau,$ | $e^{-1}$ | = | 0.368, | so $V(1\tau)$ | = | 36.8 V, | or | 36.8% |
| $t = 2\tau,$ | $e^{-2}$ | = | 0.135, | so $V(2\tau)$ | = | 13.5 V, | or | 13.5% |
| $t = 3\tau,$ | $e^{-3}$ | = | 0.050, | so $V(3\tau)$ | = | 5 V, | or | 5% |
| $t = 4t$ | $e^{-4}$ | = | 0.018, | so $V(4\tau)$ | = | 1.8 V, | or | 1.8% |
| $t = 5\tau,$ | $e^{-5}$ | = | 0.007, | so $V(5\tau)$ | = | 0.7 V, | or | 0.7% |

Here we see that after a time equal to five time constants has passed, the capacitor has discharged to less than 1% of its initial value. This is fully discharged for all practical purposes.

Another way to think of these results is that the discharge values are the complements of the charging values. Subtract either set of percentages from 100 and you will get the other set. You may also notice another relationship between the discharging values. If you take 36.8% (0.368) as the value for one time constant, then the discharged value is $0.368^2 = 0.135$ after two time constants, $0.368^3 = 0.05$ after three time constants, $0.368^4 = 0.018$ after four time constants and $0.368^5 = 0.007$ after five time constants. You can change these values to percentages, or just remember that you have to multiply the decimal fraction times the applied voltage. If you subtract these decimal values from 1, you will get the values for the charging equation. In either case, by remembering the percentage 63.2% you can generate all of the other percentages without logarithms or exponentials!

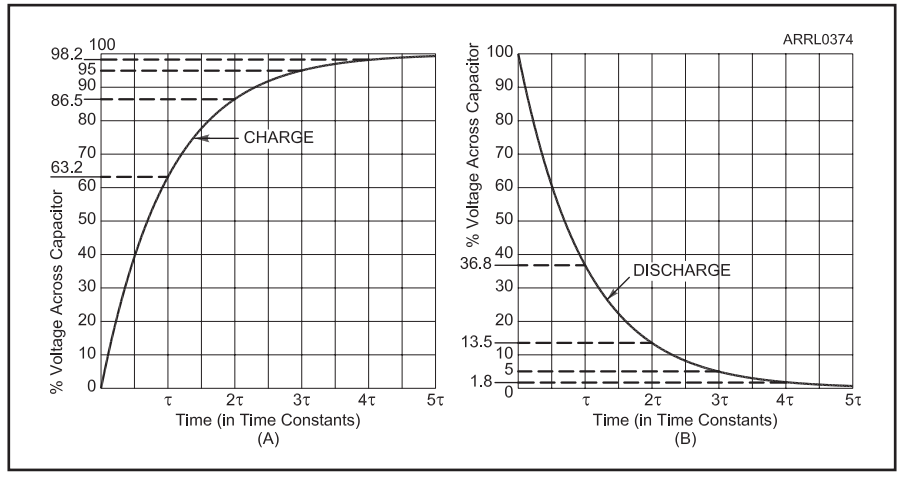

**Figure 8 — The graph at A shows how the voltage across a capacitor rises with time when charged through a resistor (an RC circuit). Graph B shows how the voltage decreases with time as the capacitor is discharged through a resistor. The dashed lines represent voltage across the capacitor after 1, 2, 3, and 4 time constants ($\tau$) have passed.**

# 6 Complex Numbers

You will frequently encounter numbers that contain the square root of minus one (–1), represented by *i* in regular mathematics. To avoid confusion with current in electronics, the symbol *j* is used instead. Since there is no real number that when squared produces –1, any number that contains *i* or *j* is called an *imaginary number*. For example, 2*j*, 0.1*j*, 7*j*/4, and 457.6*j* are all imaginary numbers.

The number *j* has a number of interesting properties:

$1/j = -j$

$j^2 = -1$

$j^3 = -j$

$j^4 = 1$

$j = 1\angle 90°$

Multiplication by *j* can also represent a phase shift of +90°.

Real and imaginary numbers can be combined by using addition or subtraction. Combining real and imaginary numbers creates a hybrid called a *complex number*, such as 1 + *j* or 6 –*j*7. (The convention in complex numbers is for *j* to be first in the imaginary part of the number.) These numbers come in very handy in radio, describing impedances, relationships between voltage and current, and many other phenomena.

If the complex number is broken up into its real and imaginary parts, those two numbers can also be used as coordinates on a graph using *complex coordinates*. This is a special type of rectangular-coordinate graph that is also referred to as the *complex plane*. By convention, the X axis coordinates represent the real number portion of the complex number and the Y axis represents the imaginary portion. For example, the complex number 6 – *j*7 would have the same location as the point (6,–7) on a rectangular-coordinate graph. **Figure 9** shows the same points as Figure 2, but now they are representing the complex numbers 3 + *j*5 and –2 – *j*4, respectively.

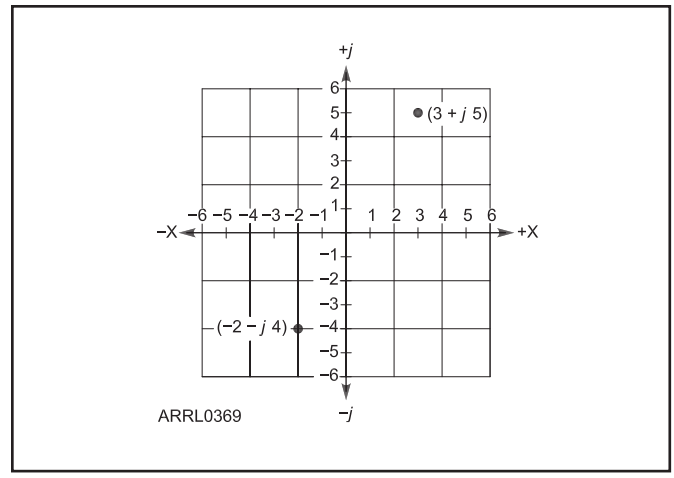

**Figure 9 — The Y axis of a complex-coordinate graph represents the imaginary portion of complex numbers. This graph shows the same numbers as in Figure 1A, graphed as complex numbers.**

## 6.1 Working With Complex Numbers

Complex numbers representing electrical quantities can be expressed in either rectangular form (a + *j*b) or polar form (r Ðθ). Adding complex numbers is easiest in rectangular form:

$(a + jb) + (c + jd) = (a + c) + j(b + d)$

Multiplying and dividing complex numbers is easiest in polar form:

$a\angle q_1 \times b\angle q_2 = (a \times b)\ (q_1 + q_2)$

and

$$\frac{a\angle\theta_1}{b\angle\theta_2} = \left(\frac{a}{b}\right)\angle\left(\theta_1 - \theta_2\right)$$

Converting from one form to another is useful in some kinds of calculations. For example, to calculate the value of two complex impedances in parallel you use the formula

$$Z = \frac{Z_1 Z_2}{Z_1 + Z_2}$$

To calculate the numerator ($Z_1Z_2$) you would write the impedances in polar form. To calculate the denominator ($Z_1 + Z_2$) you would write the impedances in rectangular form. So you need to be able to convert back and forth from one form to the other. There is a good explanation of this process, with examples, in the tutorials on complex numbers referenced in the Tutorial on Mathematics section at the end of this chapter.

Here is the short procedure you can save for reference:

To convert from rectangular (a + *j*b) to polar form (r ∠ θ):

$$r = \sqrt{(a^2 + b^2)}$$

$$\theta = \tan^{-1}\left(\frac{b}{a}\right)$$

To convert from polar to rectangular form:

$a = r \cos \theta$

$b = r \sin \theta$

Many calculators have polar-rectangular conversion functions built-in and they are worth learning how to use. Be sure that your calculator is set to the angle units you prefer, radians or degrees.

### Example

Convert 3 ∠30º to rectangular form:

$a = 3 \cos 30º = 3\ (0.866) = 2.6$

$b = 3 \sin 30º = 3\ (0.5) = 1.5$

$3\angle 30º = 2.6 + j1.5$

### Example

Convert 0.8 + *j*0.6 to polar form:

$$r = \sqrt{(0.8^2 + 0.6^2)} = 1$$

$$\theta = \tan^{-1}\left(\frac{0.6}{0.8}\right) = 36.8°$$

$0.8 + j0.6 = 1\ \angle 36.8º$

It is also common to calculate the reciprocal of a complex number. This is easiest to do in polar form. The reciprocal of a complex number $r\angle\theta$ is $(1/r)\ \angle\text{-}\theta$. When taking the reciprocal of an angle, the sign is changed from positive to negative or vice versa.

Many calculators have polar-rectangular conversion functions built-in and they are worth learning how to use. Be sure that your calculator is set to the correct units for angles, radians or degrees.

# 7 Vectors and Phasors

## Vectors

A *vector* is a quantity that has both a *magnitude* and a *direction*. In radio, the most commonly encountered vectors are used to describe impedance as a complex number (described in the previous section) and an ac signal (see the **Radio Fundamentals** chapter's discussion of Sine Waves and Rotation). For basic vector concepts, see the excellent online tutorial about vectors at **www.intmath.com/vectors/vectors-intro.php**.

Any quantity that can be represented as a complex number, can be drawn as a vector. This is described in the **Electrical Fundamentals** chapter's section on Impedance. The mathematical rules for working with vectors that have two coordinates (like impedance) are the same as for complex numbers in the previous sections. A vector is usually drawn as an arrow starting at the origin of the X-Y plane. To distinguish vectors from ordinary quantities, they are usually written in **bold** font and often with a small half-arrow above them. For example, $\vec{\mathbf{V}}$ or $\vec{\mathbf{Z}}$ are a voltage vector and an impedance vector, respectively.

Vectors can be drawn anywhere on the X-Y plane but in radio applications, they are usually shown as an arrow beginning at the origin (0,0). The arrow's length is the magnitude of the vector and the arrowhead shows the direction of the vector. For example, in the same section of the *Handbook*, Figure 2.66 (2018 edition) shows the impedance 50 + *j* 100 Ω as a vector.

AC signals can also be drawn as vectors. In this case, the magnitude of the vector is the signal's voltage (or current) and you can use peak or RMS values. (If more than one vector is being combined, the peak or RMS convention must be the same for all of them.) The direction of the vector represents phase. If all of the signals and vectors have the same frequency, the angle between the vectors represents the phase angle between the signals.

Adding vectors together graphically is very simple, as shown in **Figure 10**, by arranging the vectors "head to tail". Start by imagining all of the vectors as starting at the origin. Figure 10 shows two ac voltages, $V_A$ and $V_B$, both with the same frequency, being added together to create $V_C$.

Begin with $V_A$ and add $V_B$ to it by "moving" it (without changing its direction) so that the arrow for $V_B$ starts at the arrowhead of $V_A$. (You could also move $V_A$ to start at the end of $V_B$. The order doesn't matter.) The resulting vector, $V_C$, is drawn from the head of the first vector (at the origin) to the tail of the last vector.

Subtraction works similarly. Turn the vector to be subtracted by 180° and add as before. This is the same as subtracting an ordinary number by multiplying it by –1 and adding. Figure 10B shows what happens when $V_C$ is created by subtracting $V_B$ from $V_A$.

When impedances are combined in series and parallel circuits, their vectors are multiplied and divided according to the rules for complex numbers above. Examples of how to work with impedances and admittances in this way are given in the *Handbook*. The *Extra Class License Manual* also includes a number of examples since questions of that sort are on the exam as of 2017.

More complicated vector combinations are involved in performing modulation, mixing signals, doing transmission line calculations, and so forth. Should you need to "do the math" for these functions, you'll be well beyond what this supplement can tell you!

## Phasor Notation

When working with complex numbers, using polar notation can be much more convenient for multiplying and dividing. This is also true for vectors, where is it called *phasor notation*. For example, an impedance of 50 + *j* 100 Ω would be written 112 ∠63.4°.

Multiplying phasor A by phasor B requires you to multiply the magnitudes and add the angles:

$$V_A\angle\phi_A \times V_B\angle\phi_B = V_AV_B\angle(\phi_A + \phi_B)$$

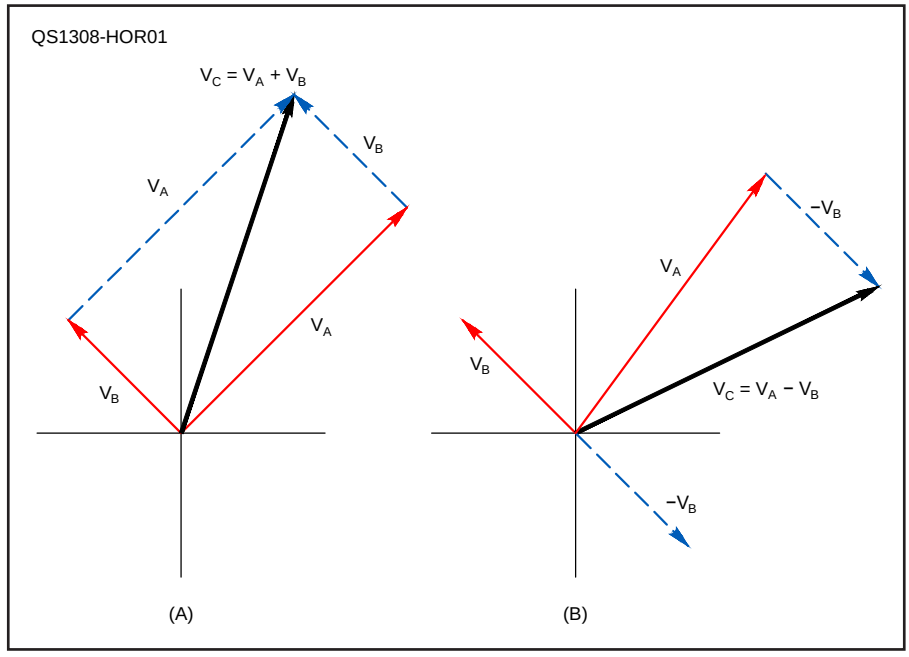

**Figure 10 — Adding and subtracting vectors. Representing voltages here, vectors can be added together (A) by placing them "head to tail" in any order. (B) shows how subtraction is performed by reversing the vector to be subtracting and then adding it as in (A).**

Similarly, to divide phasors, divide the magnitudes and subtract one angle from the other.

$$V_A\angle\phi_A \div V_B\angle\phi_B = (V_A / V_B)\angle(\phi_A - \phi_B)$$

Remember that to use phasor notation this way requires both signals to have exactly the same frequency so that $\phi_A$ and $\phi_B$ are constant. If that isn't true, these formulas cannot be used. To add phasors requires that they be converted into rectangular complex numbers (a + *j*b) first.

### Phasor Diagrams

When dealing with RF signals and circuitry, it's often true that the frequency of all signals in use is the same. Think of an RC low-pass filter, for example: the input signal $V_{IN}$ sin (ωt + 0) and output signal $V_{OUT}$ sin (ωt + ϕ) have the same frequency (ω = 2πf), even though their amplitudes are different. The filter's attenuation is given by the ratio of $|V_{OUT}| / |V_{IN}|$ and they are offset in phase by ϕ.

If the same frequency can be assumed for all signals, phasor notation can used to describe each signal as $|V| \angle\phi$ where ϕ is just the phase angle between a signal and some reference signal or phase. The input signal to a circuit is usually the reference for measuring phase differences. The form $|V| \angle\phi$ is a phasor and when drawn on an X-Y plane as vectors, the result is a *phasor diagram*. **Figure 11** is a phasor diagram showing a filter's input and output signals as phasors. The difference in length of the phasors shows the filter's attenuation and the angle between them shows the phase shift through the filter.

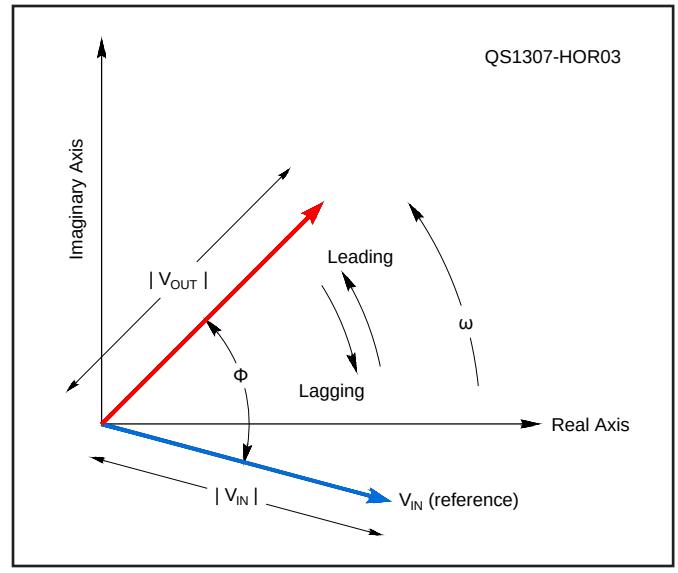

**Figure 11 — A phasor diagram showing a filter's input signal $|V_{IN}|\angle 0°$ acting as the phase reference (thus the angle of 0°) and the filter's output signal $|V_{OUT}|\angle\phi$. The frequency is the same for both signals.**

# 8 Boolean Algebra

The fundamental principle of digital electronics is that a signal can have only a finite number of discrete values or *states*. In *binary* digital systems signals may have two states, represented in *base-2 arithmetic* by the numerals 0 and 1. The binary states described as 0 and 1 may represent an OFF and ON condition or as space and mark in a communications transmission such as CW or RTTY. Since our interest in digital signals is primarily circuit-oriented, we will refer to logic circuit elements in this section.

The simplest digital devices are switches and relays. Electronic digital systems, however, are created using *digital ICs* — integrated circuits that generate, detect or in some way process digital signals. Whether switches or microprocessors, though, all digital systems use common mathematical principles known as *binary logic*. We'll start with the rules for combining different digital signals, called *combinational logic*. These rules are derived from the mathematics of binary numbers, called *Boolean algebra*, after its creator, George Boole.

In binary digital logic circuits each combination of inputs results in a specific output or combination of outputs. Except during transitions of the input and output signals (called *switching transitions*), the state of the output is determined by the simultaneous state(s) of the input signal(s). A combinational logic function has one and only one output state corresponding to each combination of input states. The output of a combinational logic circuit is determined entirely by the information at the circuit's inputs.

The simplest Boolean functions are called *elements*. Combinational logic elements may perform arithmetic or logical operations. Regardless of their purpose, these operations are usually expressed in arithmetic terms. Digital circuits add, subtract, multiply, and divide but normally do it in binary form using two states that we represent with the numerals 0 and 1.

Binary digital circuit functions are represented by equations using Boolean algebra. The symbols and laws of Boolean algebra are somewhat different from those of ordinary algebra. The symbol for each logical function is shown here in the descriptions of the individual logical elements. The logical function of a particular element may be described by listing all possible combinations in input and output values in a *truth table*.

### ONE-INPUT ELEMENTS

The *inverter* or NOT circuit (**Figure 12**) inverts a 1 at the input to produce a 0 at the output, and vice versa. NOT indicates inversion, negation or complementation. The Boolean algebra notation for the NOT function is a bar over the variable or expression, such as $B = \overline{A}$.

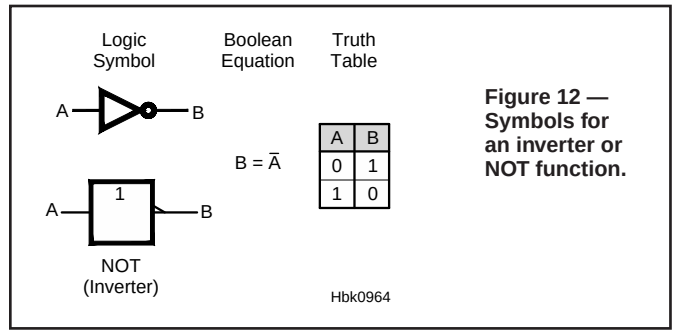

**Figure 12 — Symbols for an inverter or NOT function.**

## THE AND OPERATION

A *gate* is defined as a combinational logic element with two or more inputs and one output state that depends on the state of the inputs. Gates perform simple logical operations and can be combined to form complex switching functions. So as we talk about the logical operations used in Boolean algebra, you should keep in mind that each function is implemented by using a gate with the same name. For example, an AND gate implements the AND operation.

The AND operation results in a 1 only when all inputs or *operands* are 1. That is, if the inputs are called A and B, the output is 1 only if A and B are both 1. In Boolean notation, the logical operator AND is usually represented by a dot between the variables (•). The AND function may also be signified by no space between the variables. Both forms are shown in **Figure 13**, along with the schematic symbol for an AND gate.

## THE OR OPERATION

The OR operation results in a 1 at the output if any or all inputs are 1. In Boolean notation, the + symbol is used to indicate the OR function. The OR gate shown in **Figure 14** is sometimes called an INCLUSIVE OR. In Boolean algebra notation, a + sign is used between the variables to represent the OR function. Study the truth table for the OR function in Figure 12. You should notice that the OR gate will have a 0 output only when all inputs are 0.

## THE NAND OPERATION

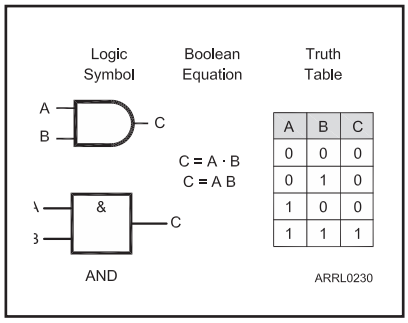
The NAND operation means NOT AND. A NAND gate (**Figure 15**) is an AND gate with an inverted output. A NAND gate produces a 0 at its output only when all inputs are 1. In Boolean notation, NAND is usually represented by a dot between the variables and a bar over the combination, as shown in Figure 13.

## THE NOR OPERATION

The NOR operation means NOT OR. A NOR gate (**Figure 16**) produces a 0 output if any or all of its inputs are 1. In Boolean notation, the variables have a + symbol between them and a bar over the entire expression to indicate the NOR function. When you study the truth table shown in Figure 16, you will notice that a NOR gate produces a 1 output only when all of the inputs are 0.

## THE EXCLUSIVE NOR OPERATION

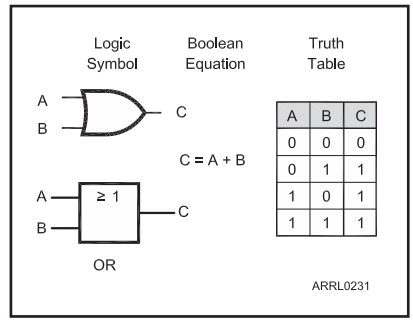
The EXCLUSIVE OR (XOR) operation (**Figure 17)** results in an output of 1 if only one of the inputs is 1, but if both inputs are 1 then the output is 0. The Boolean expression ⊕ represents the EXCLUSIVE OR function. Inverting the XOR function results in the EXCLUSIVE NOR (XNOR) operation.



## DE MORGAN'S THEOREMS

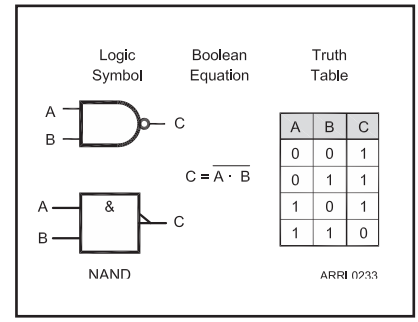
It is common to need to transform logical expressions from an expression based on the AND (•) function to one based on the OR (+) function. Although the functions were known much earlier, De Morgan expressed them in the language of modern logic in the 19th century. By repeatedly applying these rules, even complex logic equations can be transformed.

$\overline{A \cdot B} = \overline{A} + \overline{B}$



and

$\overline{A+B} = \overline{A} \cdot \overline{B}$



| A | B | C |
|---|---|---|
| 0 | 0 | 0 |
| 0 | 1 | 0 |
| 1 | 0 | 0 |
| 1 | 1 | 1 |

**Figure 13 — Symbol and Boolean equations for the AND function.**

# 9 Tutorials on Mathematics

The following web links are a compilation of online resources organized by topic. Many of the tutorials listed below are part of the Interactive Mathematics website (**www.intmath.com**), a free, online system of tutorials. The system begins with basic number concepts and progresses all the way through introductory calculus. The lessons referenced here are those of most use to a student of radio electronics.

## 9.1 Basic Numbers & Formulas

Order of Operations — **www.intmath.com/Numbers/3_Order-of-operations.php**
Powers, Roots, and Radicals — **www.intmath.com/Numbers/4_Powers-roots-radicals.php**

# Radio Math Cheat Sheet

Here are many formulas and constants that are frequently used in Amateur Radio. You can save this on your smartphone or tablet or print it out and keep it in your toolbox or on the bench. No guessing required!

### CONSTANTS

e = 2.71828; 1/e = 0.36788
π = 3.14159; 2π = 6.28318; 4π = 12.5664 ; π/2 = 1.5708; π/4 = 0.785398
$\log_{10}$ = 2.303 x ln (or $\log_e$); ln = $\log_{10}$ / 2.303

**Time constants — charging**
τ = 1/e = 0.632; 2τ = 0.865; 3τ = =0.95; 4τ = 0.982; 5τ = 0.993

**Time constants — discharging**
τ = 1=1/e = 0.368; 2τ = 0.135; 3τ = =0.05; 4τ = 0.018; 5τ = 0.007

## Ohm's Law and Power Circle

During the first semester of my *Electrical Power Technology* program, one of the first challenges issued by our dedicated instructor — Roger Crerie — to his new freshman students was to identify and develop 12 equations or formulas that could be used to determine voltage, current, resistance and power. Ohm's Law is expressed as R = E / I and it provided three of these equation forms while the basic equation relating power to current and voltage (P = I × E) accounted for another three. With six known equations, it was just a matter of applying mathematical substitution for his students to develop the remaining six. Together, these 12 equations compose the *circle* or *wheel* of voltage (E), current (I), resistance (R) and power (P)shown in **Figure A**. Just as Roger'sprevious students had learned at the Worcester Industrial Technical Institute (Worcester, Massachusetts), our Class of '82 now held the basic electrical formulas needed to proceed in our studies or professions. As can be seen in Figure A, we can determine any one of these four electrical quantities by knowing the value of any two others. You'll probably be using many of these formulas as the years go by — this has certainly been my experience.
*— Dana G. Reed, W1LC*

**Figure A — Electrical formulas**

### TABLE OF CONVERSION FACTORS FOR SINUSOIDAL AC VOLTAGE OR CURRENT

**Conversion Factors for Sinusoidal AC Voltage or Current**

| *From* | *To* | *Multiply By* |
|---|---|---|
| Peak | Peak-to-Peak | 2 |
| Peak-to-Peak | Peak | 0.5 |
| Peak | RMS | $1/\sqrt{2}$ or 0.707 |
| RMS | Peak | $\sqrt{2}$ or 1.414 |
| Peak-to-Peak | RMS | $1/(2\times\sqrt{2})$ or 0.35355 |
| RMS | Peak-to-Peak | $2\times\sqrt{2}$ or 2.828 |
| Peak | Average | 2 / π or 0.6366 |
| Average | Peak | π / 2 or 1.5708 |
| RMS | Average | $(2\times\sqrt{2})$ / π or 0.90 |
| Average | RMS | $\pi/(2\times\sqrt{2})$ or 1.11 |

Note: These conversion factors apply only to continuous pure sine waves.

### REACTANCE

$$X_C = \frac{1}{2\pi fC} \text{ and } X_L = 2\pi fL$$

### POLAR-RECTANGULAR CONVERSION

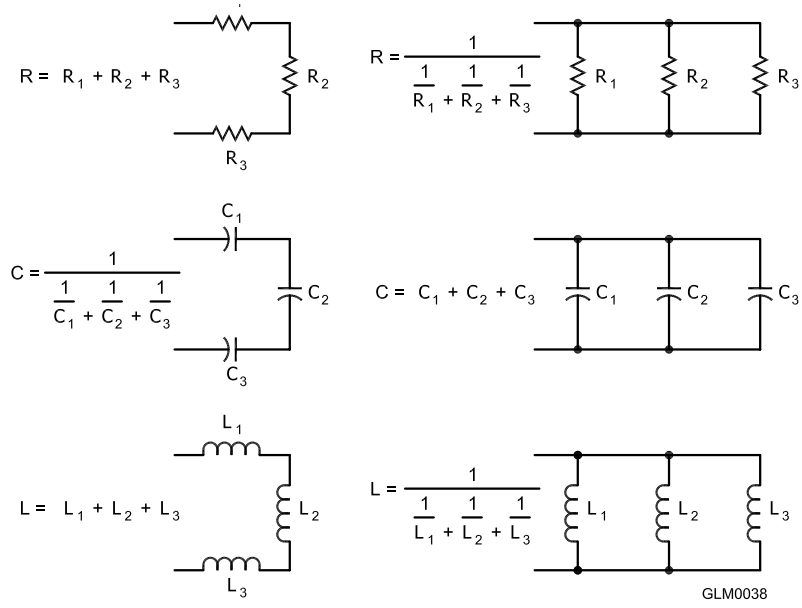
To convert from rectangular (a + *j*b) to polar form (r ∠ θ):

$$r = \sqrt{(a^2 + b^2)} \text{ and } \theta = \tan^{-1}\left(\frac{b}{a}\right)$$

To convert from polar to rectangular form:
a = r cos θ and b = r sin θ

### DECIBELS

dB = 10 log (P/ $P_{REF}$) = 20 log (V / $V_{REF}$)
Power ratio = $\log^{-1}$ (dB/10) and Voltage ratio = $\log^{-1}$ (dB/20)
dB = 10 log (percentage of power / 100) = 20 log (percentage of voltage / 100)
Percentage of power = 100% × $\log^{-1}$ (dB/10)
Percentage of voltage = 100% × $\log^{-1}$ (dB/20)
dBm: $P_{REF}$ = 1 mW; dBW: $P_{REF}$ = 1 W; dBμW: $P_{REF}$ = 1 μW
dBV: $V_{REF}$ = 1 V; dBμV: $V_{REF}$ = 1 μV
dBd = dBi - 2.15 and dBi = dBd + 2.15
1 μW = -30 dBm; 1 mW = 0 dBm; 1 W = 30 dBm
100 W = 50 dBm; 1 kW = 60 dBm



**Common dB Values For Ratios of Power and Voltage**

| *P2/P1* | *dB* | *V2/V1* | *dB* |
|---|---|---|---|
| 0.1 | -10 | 0.1 | –20 |
| 0.25 | -6 | 0.25 | –12 |
| 0.5 | -3 | 0.5 | –6 |
| 1 | 0 | 0.707 | –3 |
| 2 | 3 | 1 | 0 |
| 4 | 6 | 1.414 | 3 |
| 10 | 10 | 2 | 6 |
| | | 4 | 12 |
| | | 10 | 20 |

## PARALLEL AND SERIES COMPONENTS

**How components in series and parallel are combined into a single equivalent value. For two resistors or inductors in parallel or for two capacitors in series use the simplified formula**

$$\text{Equivalent value} = \frac{\text{Value1} \times \text{Value2}}{\text{Value1} + \text{Value2}}$$

## PEAK ENVELOPE POWER

$$PEP = \frac{\left[\frac{0.707 \times V_{Pk-Pk}}{2}\right]^2}{R_{LOAD}} = \frac{V_{RMS}^2}{R_{LOAD}}$$

## FREQUENCY-WAVELENGTH CONVERSION

Frequency (in Hz) = $3 \times 10^8$ / Wavelength (in m)
Wavelength (in m) = $3 \times 10^8$ / Frequency (in Hz)
Frequency (in MHz) = 300 / Wavelength (in m)
Wavelength (in m) = 300 / Frequency (in MHz)
Half-wavelength in free space (in feet) = 492 / Frequency (in MHz)
Quarter-wavelength in free space (in feet) = 246 / Frequency (in MHz)

## LENGTH CONVERSION

Multiply meters by 3.28 to get feet
Multiply meters by 39.4 to get inches
Multiply meters by 1.09 to get yards
Multiply yards by 0.914 to get meters
Multiply feet by 0.305 to get meters
Multiply inches by 2.54 to get centimeters
Multiply feet by 30.5 to get centimeters
Multiply centimeters by 0.0328 to get feet
Multiply centimeters by 0.394 to get inches

## TRIGONOMETRY AND ANGLES

1 radian (rad) = 57.3 degrees; $2\pi$ radians in a circle
1 degree = 0.0174 radians; 360 degrees in a circle
$45^o = \pi/4$ rad; $90° = \pi/2$ rad; $180^o = -180° = \pi$ rad
$270^o = -90° = 3/\pi/2$ rad $= -\pi/2$ rad
1 revolution = 360°; 2 rev = 720°; 3 rev = 1080°

Sin ($\theta$) = -sin ($-\theta$) = cos ($\theta - 90°$) or cos ($\theta - \pi/2$ rad)
Cos ($\theta$) = cos ($-\theta$) = sin ($\theta + 90°$) or sin ($\theta + \pi/2$ rad)

Sin (90°) = sin ($\pi/2$ rad) = cos (0) = 1
Sin (45°) = sin ($\pi/4$ rad) = cos (45°) = cos ($\pi/4$ rad) = 0.707
Sin (30°) = cos (60°) = 0.5

Sin (0) = cos (90°) = cos ($\pi/2$ rad) = 1
Sin (180°) = sin ($\pi$ rad) = 0; cos (180°) = cos ($\pi$ rad) = -1
Sin (270°) = sin ($3\pi/2$ rad) = –1; cos (270°) = cos ($3\pi/2$ rad) = 0

Tan($\theta$) = sin ($\theta$) / cos ($\theta$) = height of structure / distance to structure base
Height of a structure = distance to base of structure × tan (angle to top of structure)
Length of a guy wire =

$$\sqrt{(\text{distance to guy point})^2 + (\text{height of guy attachment})^2}$$

# *The Best of the Best*

# *Narrow Band SDR Transceiver*

# FTDX10

## Unrivaled RF Performance
## Narrow Band SDR Technology is the Revolution

**Inheriting the performance of the FTDX101, which is validated to exceed HF transceivers in laboratories around the world.**

**The most advanced digital narrow band SDR technology is combined with the RF Front-End engineering, such as the low noise-figure RF amplifier and the very sharp shape factor roofing filter designs that Yaesu has incorporated over the years, resulting in unsurpassed HF receiver performance.**

**Equipped with the latest MPVD feature, and 3DSS visual display to deliver superior Operability and Visibility.**

## A New Legend in HF Transceivers debuts

**HF/50MHz TRANSCEIVER**

**FTDX10** 100W

- The image is shown with an optional third party external display that may be connected using a DVI-D digital cable.
- Shown with Optional External Speaker SP-30.

YAESU
The radio

**YAESU USA**
6125 Phyllis Drive, Cypress,
CA 90630 (714) 827-7600

For the latest Yaesu news, visit us on the Internet: **http://www.yaesu.com**

Specifications subject to change without notice. Some accessories and/or options may be standard in certain areas. Frequency coverage may differ in some countries. Check with your local Yaesu Dealer for specific details.

## Our Handbook

**The ARRL Handbook for Radio Communications** is your complete guide to radio experimentation, discovery, and innovation. It is *the* Handbook — written by radio amateurs for everyone with a desire to advance the pursuit of wireless technology.

### Key Topics

- Radio electronics theory and principles
- Circuit design and equipment construction
- Radio signal transmission and propagation
- Digital and analog modulation and protocols
- Antennas and transmission lines
- Safe electrical, construction, and RF practices

### Always Updated! New Projects and Content...

- 3D printing for ham radio construction
- Downloadable 3D printing projects and articles
- Battery selection for portable operation
- Downloadable article — using SDR for RFI tracking
- Solid-state linear amplifier linearity
- Safe practices for antenna and tower work
- Downloadable crystal test oscillator
- Updated CAD software from Tonnesoft

**Download Included: eBook and Supplemental Content**
Download the fully searchable digital edition of the printed book, as well as expanded supplemental content, software, PC board templates, and other support files.

**System Requirements:** *Windows* 7, 8, or 10; *Windows Vista* or *Windows XP*, as well as Macintosh systems, using Adobe *Acrobat Reader* software. Acrobat Reader is a free download at **www.adobe.com**. PDF files are *Linux* readable. Other included software is *Windows* compatible only.

## About ARRL

ARRL is the national membership association for amateur radio operators in the US. ARRL has books, software, online content, and other resources for licensing, operating, and lifelong learning.

## TABLE OF CONTENTS

**Introduction**
**What is Amateur (Ham) Radio?**

**Fundamental Theory**
**Electrical Fundamentals**
**Radio Fundamentals**
**Circuits and Components**

**Practical Design and Principles**
**RF Techniques**
**Computer-Aided Circuit Design**
**Power Sources**
**DSP and SDR Fundamentals**
**Oscillators and Synthesizers**
**Analog and Digital Filtering**
**Modulation**
**Receiving**
**Transmitting**
**Transceiver Design Topics**
**Digital Protocols and Modes**
**Amateur Radio Data Platforms**
**RF Power Amplifiers**
**Repeaters**

**Antenna Systems and Radio Propagation**
**Propagation of Radio Signals**
**Transmission Lines**
**Antennas**

**Station Construction, Maintenance, and Management**
**Component Data and References**
**Construction Techniques**
**Assembling a Station**
**Test Equipment and Measurements**
**Troubleshooting and Maintenance**
**RF Interference**
**Safe Practices**

**Downloadable Content**
**Space Communications**
**Digital Communications**
**Image Communications**
**Digital Basics**
**Station Accessories and Projects**
**Annual Transceiver Survey**

# Supplemental Files – 2022 ARRL Handbook

Supplemental files available online include additional discussion, related articles, additional projects, full-size PC board etching patterns and templates, program examples, construction details and other useful information. (Note: Chapter 1 has no supplemental files.)

## Chapter 2

### Articles

- Hands On Radio: Kirchoff's Laws by Ward Silver, NØAX
- Hands On Radio: Laying Down the Laws by Ward Silver, NØAX
- Hands On Radio: Putting the Laws to Work by Ward Silver, NØAX
- Hands On Radio: Thevenin Equivalents by Ward Silver, NØAX
- Radio Math Formulas and Notes — a cheat sheet with formulas and tables
- Radio Mathematics — supplemental information about math used in radio and a list of online resources and tutorials about common mathematics
- Scientific and Engineering Notation by Walter Banzhaf, WB1ANE
- Understanding a Scientific Calculator by Walter Banzhaf, WB1ANE

## Chapter 3

### Articles

- Digital Electronic Basics by Dale Botkin, NØXAS
- Hands On Radio: Maxwell's Equations — Grad, Div, and Curl by Ward Silver, NØAX
- Hands On Radio: Maxwell's Equations — The Wave Emerges by Ward Silver, NØAX
- Hands On Radio: The Effects of Gain-Bandwidth Product by Ward Silver, NØAX
- Maxwell Without Tears by Paul Shuch, N6TX
- Untangling the Decibel Dilemma — Expanded by Ward Silver, NØAX

*Also see these articles with the Chapter 2 Downloadable Content:*

- Radio Mathematics
- Radio Math Formulas and Notes

### Tools and Data

- Frequency Response Spreadsheet

## Chapter 4

### Articles

- Hands On Radio: Basic Operational Amplifiers by Ward Silver, NØAX
- Hands On Radio: Field Effect Transistors by Ward Silver, NØAX
- Hands On Radio: Load Lines by Ward Silver, NØAX
- Hands On Radio: The Common Base Amplifier by Ward Silver, NØAX
- Hands On Radio: The Common Emitter Amplifier by Ward Silver, NØAX
- Hands On Radio: The Emitter-Follower Amplifier by Ward Silver, NØAX
- Large Signal Transistor Operation

### Tools and Data

- *LTSpice* Simulation Files
- Frequency Response Spreadsheet

## Chapter 5

### Articles

- Designing Wide-band Transformers for HF and VHF Power Amplifiers by Chris Trask, N7ZWY
- Reflections on the Smith Chart by Wes Hayward, W7ZOI
- Simplified Design of Impedance-Matching Networks, Parts I through III by George Grammer, W1DF
- The Galactic Background in the Upper HF Band by Dave Typinski, AJ4CO

### Tools and Data

- *LTSpice* simulation files for Effects of Parasitic Characteristics (Section 5.3)
- *MATCH.EXE* software (for use with Tuned (Resonant) Networks discussion)

## Chapter 6

### Articles

- Circuit Simulation Examples by David Newkirk, W9VES
- Color images for the Electromagnetic Analysis of RF Circuits section
- Mathematical Stability Problems in Modern Non-Linear Simulation Programs by Dr. Ulrich Rohde, N1UL and Rucha Lakhe
- The Dangers of Simple Usage of Microwave Software by Dr. Ulrich Rohde, N1UL and Hans Hartnagel
- Using Simulation at RF by Dr. Ulrich Rohde, N1UL

### Tools and Data

- SON and data files for the Electromagnetic Analysis of RF Circuits section

## Chapter 7

### Articles

- Testing and Monitoring Batteries — Excerpts from *Batteries in a Portable World* by Isidor Buchmann
- Vacuum Tube and Obsolete Rectifiers

### Projects

- 12 V 15 A Power Supply — Article and PCB Template
- 13.8 V 5 A Power Supply — PCB Template
- A Deluxe High Voltage Supply by James Garland, W8ZR
- A Small, Lightweight High-Voltage Switch-Mode Power Supply by Ralph Crumrine, NØKC
- Build an Inverting DC-DC Converter by Jim Stewart
- Diode Voltage Drops Raise Battery Power Drain by Ward Silver, NØAX
- Four Output Bench Supply by Larry Cicchinelli, K3PTO — Article and support files
- Overvoltage Crowbar Circuit
- Power Gadgets from USB Sources with the Simple Switching Boost Supply by Tom Wheeler, NØGSG
- Revisiting the 12 V Power Supply
- Simple Adjustable Tracking Power Supply by Bryant Julstrom, KCØZNG

## Chapter 8

### Articles

- SDR Simplified — Fourier Transforms by Ray Mack, W5IFS
- SDR Simplified — Fundamentals of Sampling by Ray Mack, W5IFS
- SDR Simplified — More on Sampling by Ray Mack, W5IFS

## Chapter 9

### Articles

- An Optimized Grounded Base Oscillator Design for VHF/UHF
  by Dr. Ulrich Rohde, N1UL, and Ajay Poddar, AC2KG
- Automatic Tracking Filter for DDS Generator by Riccardo Gionetti, IØFDH
- Calculation of FM and AM Noise Signals of Colpitts Oscillators in the Time Domain by Dr. Ulrich Rohde, N1UL
- Crystal Test Oscillators by Fred Brown, W6HPH
- Frequency Synthesis: Current and Future Projections by Alexander Chenakin
- Measuring Receiver Phase Noise
- Novel Grounded Base Oscillator Design for VHF-UHF by Dr. Ulrich Rohde, N1UL
- Optimized Oscillator Design by Dr. Ulrich Rohde, N1UL
- Oscillator Design Using *LTSpice* by David Stockton, GM4ZNX
  (also see *LTSpice* simulation files in SwissRoll folder)
- Oscillator Phase Noise by Dr. Ulrich Rohde, N1UL
- Programming the DDS AD9850 Signal Generator Module
  by James Kretzschmar, AE7AX
- Simulation of the Low Noise Oscillator from Solid State Design for the Radio Amateur by Linley Gumm, K7HFD
- Some Thoughts on Crystal Oscillator Design by Dr. Ulrich Rohde, N1UL
- Some Thoughts on Designing Very High Performance VHF Oscillators
  by Dr. Ulrich Rohde, N1UL
- What You Always Wanted to Know About Colpitts Oscillators
  by Dr. Ulrich Rohde, N1UL, and Anisha M. Apte

### Tools and Data

- Simulation files for Oscillator Design Using *LTSpice* (SwissRoll folder)

## Chapter 10

### Articles

- 6-Meter Filter with Harmonic Suppression by Paul Wade, W1GHZ
- A High Performance, Low Cost 1.8 to 54 MHz Low Pass Filter by Bill Jones, K8CU
- Altoids Tin Filters by Paul Wade, W1GHZ
- An Easy-to-Build, High-Performance Passive CW Filter by Ed Wetherhold, W3NQN
- Band-Pass Filters for HF Transceivers by Lew Gordon, K4VX
- Combline Filters for VHF and UHF by Paul Wade, W1GHZ
- Crystal Filter Design and Crystal Characterization
- Crystal Parameter Measurements Simplified by Chuck Adams, K7QO
- Hands On Radio: *ELSIE* Filter Design — Parts 1 and 2 by Ward Silver, NØAX
- HF Yagi Triplexer Especially for Field Day by Gary Gordon, K6KV
- High-Power HF Band-Pass Filter Design by Jeff Crawford, KØZR
- Improved Audio-Frequency Bandpass Filter for Morse Code Reception
  by Jim Tonne, W4ENE
- Manual Filter Design Examples by Jim Tonne, W4ENE
- SDR Simplified — Cascaded Integrator Comb Filters by Ray Mack, W5IFS
- SDR Simplified — Filter Design Program by Ray Mack, W5IFS
- SDR Simplified — Fourier Transforms by Ray Mack, W5IFS
- SDR Simplified — More Filter Activities by Ray Mack, W5IFS
- Using Active Filter Design Tools by Dan Tayloe, N7VE

*Note: Also see the Windows software by Jim Tonne, W4ENE, in the separate Software folder*

## Chapter 11

### Articles

- About FM by Ward Silver, NØAX
- About SSB by Ward Silver, NØAX
- Emissions Designator Table
- Modulation Glossary
- SDR Simplified — Introduction to I and Q by Ray Mack, W5IFS

## Chapter 12

### Articles

- HF Receiver Testing by Adam Farson, VA7OJ/AB7OJ
- Noise Power Ratio (NPR) Testing on HF Receivers by Adam Farson, VA7OJ/AB7OJ
- Performance Capability of Active Mixers by Dr. Ulrich Rohde, N1UL
- SDR Simplified — Filter Design Program by Ray Mack, W5IFS
- SDR Simplified — Introduction to CIC Filters by Ray Mack, W5IFS
- SDR Simplified — More Filter Activities by Ray Mack, W5IFS
- SDR Simplified — Nyquist Meets Real World by Ray Mack, W5IFS
- VHF and UHF Receivers and UHF and Microwave Techniques

*Also see articles with the Chapter 13 and 14 Downloadable Content*

### Projects

- 10 GHz preamp PCB template by Zack Lau, W1VT
- A Dual Band Low Noise Amplifier for 2 Meters and 70 Centimeters
  by Jim Kocsis, WA9PYH
- A High Performance 45 MHz IF Amplifier for an Up-Conversion HF/LF Receiver
  by Colin Horrabin, G3SBI
- A Long-wave Upconverter by Fred Brown, W6HPH
- A Software-Based Remote Receiver Solution by Martin Ewing, AA6E
- A Software Controlled Radio Preselector by J. Onate, MØWWA and X. de Fortuny
- All Mode 1 kHz to 1.7 GHz SDR Receiver by James Forkin, WA3TFS
- Binaural I-Q Receiver project by Rick Campbell, KK7B

- General Coverage Preselector by George Hirshfield, W5OZF
- Receiver projects from previous editions of the ARRL Handbook
- Rock Bending Receiver PCB template by Randy Henderson, WI5W
- Simple SDR Receiver by Michael Hightower, KF6SJ
- Tunable RF Preamplifier Using Varicap Diode by George Steber, WB9LVI
- Universal MMIC Preamp by Paul Wade, W1GHZ

## Chapter 13

### Articles

- Clean, Punchy, Competitive Contest Audio Without Splatter by Jim Brown, K9YC
- SDR Simplified — Demystifying PID Control Loops by Ray Mack, W5IFS
- SDR Simplified — Noise Reduction and Adaptive Filters by Ray Mack, W5IFS
- Speech Processing: Some New Ideas by Jim Tonne, W4ENE

*Also see articles with the Chapter 12 and 14 Downloadable Content*

### HF Transmitter and Transceiver Projects

- A Fast TR Switch by Jack Kuecken, KE2QJ
- Designing and Building Transistor Linear Power Amplifiers Parts 1 and 2 by Rick Campbell, KK7B
- MicroT2 — A Compact Single-Band SSB Transmitter by Rick Campbell, KK7B
- MkII — An Updated Universal QRP Transmitter by Wes Hayward, W7ZOI
- TAK-40 SSB/CW Transceiver by Jim Veatch, WA2EUJ
- The Rockmite — A Simple Single-Band CW Transceiver by Dave Benson, K1SWL (article and folder with HEX file)
- The Tuna Tin 2 Today by Ed Hare, W1RFI
- Transmitter and transceiver projects from previous editions of the ARRL Handbook

### VHF/UHF Transmitter and Beacon Projects

- A 2-Meter Transmitter for Fox Hunting by Mark Spencer, WA8SME
- A Microwave Transverter Controller by Hamish Kellock, OH2GAQ
- CW Beacon Exciter for 50 MHz by Michael Sapp, WA3TTS (article and parts list)

- Simple Frequency Doublers with High Performance by Paul Wade, W1GHZ
- VHF and UHF CW Beacons by Michael Sapp, WA3TTS
- VHF Open Sources by Rick Campbell, KK7B (article and parts placement)

## Chapter 14

*Also see articles with the Chapter 12 and 13 Downloadable Content*

**Software Defined Radio and DSP Articles and Projects**

- Build Your Own IF SDR by Alex Schwarz, VE7DXW and Guy Roels, ON6MU
- Chapter 14 — Audio Oscillator example.grc (*GNU Radio* design file)
- Digital Signal Processing and GNU Radio Companion by John Petrich, W7FU and Tom McDermott, N5EG
- Digital Signal Processing (DSP) Projects: Examples of GNU Radio and GRC Functionality by John Petrich, W7FU, and Tom McDermott, N5EG
- Hands On SDR — FPGAs by Scotty Cowling, WA2DFI
- Hands On SDR — Introduction by Scotty Cowling, WA2DFI
- Hands On SDR — More on FPGAs by Scotty Cowling, WA2DFI
- Hands On SDR — Sharing Radios on the Network by Scotty Cowling, WA2DFI
- Hands On SDR — Using FPGAs in SDR Designs by Scotty Cowling, WA2DFI
- Hardware Building Blocks for High Performance SDRs by Scotty Cowling, WA2DFI
- SDR Simplified — Demystifying PID Control Loops by Ray Mack, W5IFS
- SDR Simplified — Step One Toward a Working SDR by Ray Mack, W5IFS

**Transverter Articles and Projects**

- A 222 MHz Transverter for the Yaesu FT-817 by Paul Wade, W1GHZ
- A 222 MHz Transverter for the Yaesu FT-817 — Revisited by Paul Wade, W1GHZ
- Assembling a Microwave Transverter System by Paul Wade, W1GHZ
- Cheap & Simple 1296 MHz Transverter Update by Paul Wade, W1GHZ
- Corrections and Improvements for Simple and Cheap Multiband Microwave Transverters, by Paul Wade, W1GHZ
- Sequencers for Transverter Control by Paul Wade, W1GHZ
- Smart Fool-resistant Conditional Sequencer, by Paul Wade, W1GHZ

- The Transverter — An Introduction to a Useful Device by Bill Wageman, K5MAT
- The Transverter, by Tom Williams, WA1MBA
- Universal MMIC Preamp, by Paul Wade, W1GHZ

## Chapter 15

### Articles and Data Tables

- ASCII Character Code Table
- Digital Modes — Lowest Permitted Amateur Frequency
- High-Speed Wireless Networking in the UHF and Microwave Bands
  by David Bern, W2LNX, and Keith Elkin, KB3TCB
- ITA2 Character Code Table
- Operating Tips for Digital Voice Using *FreeDV* by Mel Whitten, KØPFX
- The FT4 and FT8 Communication Protocols by Steve Franke, K9AN,
  Bill Somerville, G4WJS, and Joe Taylor, K1JT
- Varicode tables for PSK31, MFSK16 and DominoEX

## Chapter 16

### Articles

- A Simple Sensor Package for High Altitude Ballooning by John Post, KA5GSQ
- APRS Unveiled by Bob Simmons, WB6EYV
- APRS with a Smartphone by Pat Cain, KØPC
- ARRL Education and Technology Program Space/Sea Buoy
  by Mark Spencer, WA8SME
- Fox-1 Satellite Telemetry – Part 1: On the Satellite, by Burns Fisher, W2BFJ
- Fox-1 Satellite Telemetry – Part 2: FoxTelem, by Chris Thompson, AC2CZ
- Touching Near Space on a Budget by Paul Verhage, KD4STH
- High Altitude Platforms - folder with a collection of Powerpoint presentations
  and PDF articles by Paul Verhage, KD4STH

## Chapter 17

### Articles

- A Tube Tester for High Power Transmitting Tubes by John Mathis, WA5FAC, and Max Landey, KM4UK
- Amplifier Overshoot-Drive Protection by Phil Salas, AD5X
- Amplifier Projects from Previous Handbook Editions
- Design Example — HF Amplifier using 8877 Vacuum Tube by John Stanley, K4ERO
- Design Example — MOSFET Thermal Design by Dick Frey, K4XU
- Designing to Avoid Interactive Tuning and Load Adjustments by John Stanley, K4ERO
- Determining a Transistor's Power Rating (APT Application Note) by Dick Frey, K4XU

### HF Amplifier Projects

- 250 W Broadband Solid-State Linear Amplifier by Dick Frey, K4XU (including files with construction notes and photos, PCB layouts, parts lists, etc.)
- 3CX1500D7 RF Linear Amplifier by Jerry Pittenger, K8RA (including PCB layout, Pi-L values spreadsheet, etc.)
- The Everyham's Amp by John Stanley, K4ERO (including files with construction notes, layouts, use of different tubes, etc.)
- Sunnyvale/Saint Petersburg Kilowatt-Plus, a 4CX1600B HF amplifier project by George Daughters, K6GT

### VHF Amplifier Projects

- 144 MHz Amplifier Using the 3CX1200Z7 by Russ Miller, N7ART
- A 6 Meter Kilowatt Amplifier by Dick Stevens, W1QWJ
- Build a Linear 2 Meter, 80 W All Mode Amplifier by James Klitzing, W6PQL
- Design Notes for 'A Luxury Linear' Amplifier by Mark Mandelkern, K5AM
- High-Performance Grounded-Grid 220-MHz Kilowatt Linear by Robert Sutherland, W6PO
- Simple Broadband Solid-State Power Amplifiers by Paul Wade, W1GHZ

**UHF/Microwave Amplifier Projects**

- 2 Watt RF Power Amplifier for 10 GHz by Steven Lampereur, KB9MWR
- 432 MHz 3CX800A7 Amplifier by Steve Powlishen, K1FO
- 2304 MHz 70 W Rover Amplifier by Bill Koch, W2RMA, and John Brooks, N9ZL
- A High-Power Cavity Amplifier for the New 900-MHz Band
  by Robert Sutherland, W6PO
- A Quarter-Kilowatt 23-cm Amplifier Parts 1 and 2 by Chip Angle, N6CA

**Software and Tools**

- 135 Degree Pi Network Calculator Spreadsheet by John Stanley, K4ERO
- MATCH.EXE and information on Tuned (Resonant) Networks

*The following programs are available in the separate Software folder*

- *TubeCalculator* by Bentley Chan and John Stanley, K4ERO,
  for analysis of operation of popular high power transmitting tubes.
- *PI-EL* by Jim Tonne, W4ENE, for design and analysis of pi and pi-L
  networks for transmitter output.
- *MeterBasic* by Jim Tonne, W4ENE, for design and printing of custom analog meter scales.

## Chapter 18

- Glossary of FM and Repeater Terminology

## Chapter 19

### Articles

- Build a Homebrew Radio Telescope by Mark Spencer, WA8SME
- F-Region Propagation and the Equatorial Ionosphere Anomaly
  by Jim Kennedy, K6MIO/KH6
- Gray Line Propagation, or Florida to Cocos (Keeling) on 80m by Ed Callaway, N4II
- Hands On Radio: Recording Signals by Ward Silver, NØAX
- The New Sunspot Numbers by Carl Luetzelschwab, K9LA
- The Penticton Solar Flux Receiver by John White, VA7JW and Ken Tapping
- The Reverse Beacon Network by Pete Smith, N4ZR and Ward Silver, NØAX
- The Solar Eclipse QSO Party by Ward Silver, NØAX
- Upper Level Lows and 6-Meter Sporadic E by Joe Dzekevich, K1YOW
- What to Expect During the Rising Years of Solar Cycle 25
  by Frank Donovan, W3LPL

## Chapter 20

### Articles

- A Commercial Triplexer Design by George Cutsogeorge, W2VJN
- Chokes and Isolation Transformers for Receiving Antennas by Jim Brown, K9YC
- Don't Blow Up Your Balun by Dean Straw N6BV
- HF Yagi Triplexer Especially for ARRL Field Day by Gary Gordon, K6KV
- Legacy Wound-Coax Ferrite Chokes
- Measuring Ferrite Chokes by Jim Brown, K9YC
- Measuring Isolation Between Radios by George Cutsogeorge, W2VJN
- Microwave Plumbing by Paul Wade, W1GHZ
- Multiband Operation with Open-Wire Line by George Cutsogeorge, W2VJN
- Octave for Complex Characteristic Impedance by Maynard Wright, W6PAP
- Optimizing the Performance of Harmonic Attenuation Stubs
  by George Cutsogeorge, W2VJN
- Optimizing the Placement of Stubs for Harmonic Suppression by Jim Brown, K9YC
- Radio Frequency (RF) Surge Suppressor Ratings for Transmissions into
  Reactive Loads by Gene Hinkle, K5PA
- Simple Splice for 7/8 Inch Heliax by Ott Fiebel, W4WSR
- Smith Chart Supplement
- Splicing Window Line by Joel Hallas, W1ZR
- Transmission Lines in Digital Circuits
- Using *TLW* to Design Impedance Matching Networks
  by George Cutsogeorge, W2VJN

### Software and Tools

- *MATCH.EXE* software (for use with Tuned (Resonant) Networks discussion)

*The following program is available in the separate Software folder*

- *jjSmith* from Tonne Software

## Chapter 21

### Articles

- A Simple Direction-Finding Receiver for 80 Meters by Dale Hunt, WB6BYU
- Design of a Two-band Loaded Dipole Antenna by David Birnbaum, K2LYV
- Direction Finding Techniques by Joe Moell, KØOV
- Half-Wave and Multiband Dipole Azimuth and Elevation Patterns
- Weatherizing Outdoor Inductors and Traps by Dick Sander, K5QY
- Workshop Chronicles: Alloy Designations by Don Daso, K4ZA

### HF Projects

- A Compact Multiband Dipole by Zack Lau W1VT
- A No Compromise Off-Center Fed Dipole for Four Bands by Rick Littlefield, K1BQT
- An Off-Center End-Fed Dipole for Portable Operation on 40 to 6 Meters
  by Kai Siwiak, KE4PT
- Extended Double-Zepp for 17 Meters
- Five-Band Two-Element Quad by Al Doig, W6NBH, and William Stein, KC6T
- Having a Field Day with the Moxon Rectangle by L.B. Cebik, W4RNL
- The J78 Antenna: An Eight-band Off-Center-Fed HF Dipole
  by Brian Machesney, K1LI/J75Y
- The Trimox — A Moxon Tribander for a Holiday DXpedition
  by Brian Machesney, K1LI
- The W4SSY Spudgun by Byron Black, W4SSY
- Top-Loaded Low-Band Antenna Construction Details by Dick Stroud, W9SR
- Triband Dipole for 30, 17, and 12 Meters by Zack Lau W1VT
- Two-Band Loop for 30 and 40 Meters by James Brenner, NT4B
- Two W8NX Multiband, Coax-Trap Dipoles
- Wire Quad for 40 Meters by Dean Straw, N6BV

### VHF and UHF Projects

- 6-Meter Halo Antenna for DXing by Jerry Clement, VE6AB
- A New Spin on the Big Wheel by L.B. Cebik, W4RNL, and Bob Cerreto, WA1FXT

- A Simple Fixed Antenna for VHF/UHF Satellite Work by L.B. Cebik, W4RNL
- A Small 70-cm Yagi by Zack Lau, W1VT
- A True Plumber's Delight for 2 Meters — An All-Copper J-Pole
  by Michael Hood, KD8JB
- Cheap Antennas for the AMSAT LEOs by Kent Britain, WA5VJB
- Dual-Band Antenna for 146/446 MHz by Wayde Bartholomew, K3MF
- Medium-Gain 2 Meter Yagi by L.B. Cebik, W4RNL
- Quick and Cheap Omni Antenna for 1296 MHz by Paul Wade, W1GHZ

## Chapter 22

### Data Tables and Connector Instructions

- BNC Crimp Installation Instructions
- F Compression Installation Instructions
- Miniature Lamp Guide
- N Crimp Installation Instructions
- Obsolete RF Power Semiconductor Tables
- Thermoplastics Properties
- TV Deflection Tube Guide

### Reference Tables and Abbreviations

*(these items are in a single PDF file)*

- ·US Customary Units and Conversion Factors
- Metric System — International System of Units (SI)
- ·Voltage-Power Conversion Table
- Reflection Coefficient, Attenuation, SWR, and Return Loss
- Abbreviations List

## Chapter 23

### Articles

- 3D Printed Antennas by Paul Wade, W1GHZ
- 3D Printed Coax-to-Wire Connection Blocks by John Portune, W6NBC
- 3D Printed Fixture Simplifies Ground-Plane Antenna Construction
  by John Portune, W6NBC
- A No-Special-Tools SMD Desoldering Technique by Wayne Yoshida, KH6WZ
- Introduction to 3D Printing for Hams by John Portune, W6NBC
- Making Your Own Printed Circuit Boards
- Reflow Soldering for the Radio Amateur by Jim Koehler, VE5JP
- Reflow Soldering for the Radio Amateur — Revisited by Jim Koehler, VE5FP
- Repurposing Obsolete Instrument Enclosures by Scott Roleson, KC7CJ
- Soldering Surface-Mount Devices by Dino Papas, KLØS
- Surface Mount Technology — You Can Work With It (Parts 1 - 4)
  by Sam Ulbing, N4UAU

## Chapter 24

### Articles

- A Look at Gasoline Powered Inverter Generators by Bob Allison, WB1GCM
- Field Day Towers — Doing it Right, by Don Daso K4ZA and Ward Silver, NØAX

## Chapter 25

### Articles

- Antenna Analyzer Pet Tricks by Paul Wade, W1GHZ
- Apparatus for RF Measurements by Bruce Pontius, NØADL, and Kai Siwiak, KE4PT
- ARRL Lab Test Procedures Manual
- Build a Return Loss Bridge by James Ford, N6JF
- E- and H-Field Probes by Ward Silver, NØAX
- Low Frequency Adapter for your Vector Network Analyzer (VNA)
  by Jacques Audet, VE2AZX
- Noise Instrumentation and Measurement by Paul Wade W1GHZ
- RF Field Strength Meter by John Noakes, VE7NI
- RF Sampler Construction details by Thomas Thompson, WØIVJ
- RF Step Attenuator by Denton Bramwell, K7OWJ
- Test and Measurement Bibliography
- Test and Measurement Further Reading
- Test and Measurement Glossary
- Two-Tone Oscillator — PCB artwork and layout graphics — ARRL Lab

- Receiver Testing and Performance by Rob Sherwood, NCØB *(separate folder)*
  - Receiver Noise Floor and Band Noise
  - Reciprocal Mixing Test Procedure
  - Sherwood Lab Setup for Dynamic Range Measurements
  - Terms Explained for the Sherwood Table of Receiver Performance

### Project Files (Separate Folders)

- Compensated RF Voltmeter articles by Sidney Cooper, K2QHE
- Gate Dip Oscillator articles and PCB artwork by Alan Bloom, N1AL
- Logic Probe — supporting photos and graphics by Alan Bloom, N1AL
- RF Power Meter — supporting files by William Kaune, W7IEQ
- Tandem Match articles by John Grebenkemper, KI6WX
- Transistor Tester — PCB artwork and layout graphics by Alan Bloom, N1AL

## Chapter 26

### Articles

- Amplifier Care and Maintenance by Ward Silver, NØAX
- Building a Modern Signal Tracer by Curt Terwilliger, W6XJ
- Diode and Transistor Test Circuits by Ed Hare, W1RFI
- Hands On Radio: Power Supply Analysis by Ward Silver, NØAX
- Troubleshooting Radios by Mel Eiselman, NC4L

### PC Board Templates

- AF/RF signal injector template
- Crystal controlled signal source template

## Chapter 27

### Articles

- Building Contest Scores by Killing Receive Noise — Parts 1 and 2
  by Jim Brown, K9YC
- Can Home Solar Power and Ham Radio Coexist? by Tony Brock-Fisher, K1KP
- Tracking RFI with an SDR Once Source at a Time by Alan Higbie, KØAV
- TV Channel, Amateur Band and Harmonic Chart
- What to Do if You Have an Electronic Interference Problem — *CEA Handbook*

### Projects

- A Home-made Ultrasonic Power Line Arc Detector by Jim Hanson, W1TRC
- A Home-made Ultrasonic Power Line Arc Detector Project Update
  by Jim Hanson, W1TRC
- A Simple TRF Receiver for Tracking RFI by Rick Littlefield, K1BQT
- Active Attenuator for VHF-FM by Fao Eenhoorn, PAØZR (article and template)
- Handheld Loop Antenna for RFI Location by Gary Johnson, NA6O
- RF Sniffer Construction Notes by Mark Kupferschmid, AC9PR
- Simple Seeker by Dave Geiser, W5IXM
- Tape Measure Beam for Power Line Hunting by Jim Hanson, W1TRC

## Chapter 28

### Articles

- *Electric Current Abroad* — U.S. Dept of Commerce
- Field Day Tower Safety by Don Daso, K4ZA and Ward Silver, NØAX
- RF Safety at Field Day by Greg Lapin, N9GL
- RF Surge Suppressor Ratings for Transmissions into Reactive Loads
  by Gene Hinkle, K5PA
- Shop Safety by Don Daso, K4ZA

## Image Communications

- Educational robot ATV setup details (BOE-BOT project) by Mark Spencer, WA8SME

## Space Communications

- Devilish Doppler: Critical Knowledge for Successful EME on the Higher Bands
  by Al Katz, K2UYH
- Galactic Background in the Upper HF Band by Dave Typinski, AJ4CO
- SatNOGS: Satellite Networked Open Ground Station by Daniel White, ADØCQ
- Working Digipeaters with the Kenwood TH-D72A and TH-D74A
  by Joe Kornowski, KB6IGK and Patrick Stoddard, WD9EWK

## Station Accessories and Projects

### Projects

- A Digital Interface in Time for Field Day by Julian Moss, G4ILO
- A Low-Cost Remote Antenna Switch by Bill Smith, KO4NR
- A Raspberry Pi Network Server/Client for Antenna Rotor, by Tom Doyle, W9KE
- A Remote Power Controller by Mike Bryce, WB8VGE
- A Switched Attenuator courtesy of RSGB
- Adapting Aviation Headsets to Ham Radio
- An Arduino-based Knob Box for SDR by Michael Stott, VE3EBR
- Arduino CW Serial IDer by Bob Anding, AA5OY (plus software/support files)
- Audio Splitter by Glenn Loake, GØGBI
- Bistable Transfer Relay by Oliver Nicic, DG7XO
- Build a Legal Limit Bias T that Covers 1.8 to 230 MHz by Phil Salas, AD5X
- Digital 10 W Stereo Audio Amplifier by Helmut Berka, DL2MAJ and Wolfgang Fortsch, DK4MZ
- Eight Channel Remote Control Antenna Selector by Michael Dzado, ACØHB
- ID-O-Matic Station Identification Timer by Dale Botkin, NØXAS (plus source code and support files, separate folder)
- Multiband Tuning Circuits by R. W. Johnson, W6MUR
- PICAXE-Based Timer by Darrell Davis, KT4WX (plus software/support files)
- Tandem Match—Accurate Directional Wattmeter by John Grebenkemper, KI6WX
- Two QSK Controllers for Amplifiers by Jim Colville, W7RY and Paul Christensen, W9AC (plus source code and support files, separate folder)

### Support Files

- SWR Monitor by Larry Coyle, K1QW support files (ZIP file)
- Trio of Computer Interfaces PCB template
